Vacuum Elasticity as Universal Regulator: Shear Modulus $\Xi = c^4/(8\pi G)$

Vacuum Damping:
From Structure Formation to Cosmological Bounce

Abstract

Cosmological simulations and analytical treatments are subject to several fundamental divergences, including ultraviolet (UV) pathologies in perturbative expansions, shell-crossing singularities in N-body integrations, cusp-like divergences in dark matter halo density profiles, and geodesic incompleteness in models of gravitational collapse. The conventional strategy for addressing these issues is to introduce phenomenological (ad hoc) regularization parameters, which are subsequently tuned to reproduce observational data.

In this work, an alternative framework is proposed based on the introduction of a nonlinear damping term of the form $\lambda|v|^\alpha v$, where the damping coefficient is fixed by

$$\lambda = \frac{G}{c^3},$$

derived from the hypothesis that the vacuum behaves as an elastic medium characterized by a shear modulus

$$\Xi = \frac{c^4}{8\pi G}.$$

Both λ and Ξ are thereby determined uniquely by fundamental constants, eliminating the need for empirical calibration.

Within this framework, it is demonstrated that: (1) shell-crossing singularities in Lagrangian perturbation theory are regularized while preserving the positivity of the Jacobian determinant of the Lagrangian map; (2) the cusp–core discrepancy in halo density profiles is mitigated via a modified Schrödinger–Poisson system; (3) a nonsingular cosmological bounce replaces the Big Bang singularity at densities on the order of the Planck density, $\rho \sim \rho_P$; and (4) the stability of numerical schemes is enhanced without recourse to stochastic subgrid parameterizations.

The proposed approach provides a unifying description of several previously disparate regularization mechanisms within the framework of the Theory of Temporal Spheres, which models the vacuum as an elastic continuum endowed with well-defined mechanical properties.

1 Introduction

1.1 Hierarchy of Scales

Physical processes in the Universe span a range of scales exceeding sixty orders of magnitude.

$$\ell_P \sim 10^{-35}\,\mathrm{m} \quad \longrightarrow \quad R_H \sim 10^{26}\,\mathrm{m}, \tag{1}$$

where $\ell_P = \sqrt{\hbar G/c^3}$ is the Planck length and $R_H = c/H_0$ is the Hubble radius. Between these limits lies all observable structure: from quantum vacuum fluctuations to galaxy superclusters and the large-scale cosmic web.

No computational method can resolve this entire range. Modern cosmological simulations operate at intermediate scales:

$$\Delta x_{\mathrm{sim}} \sim 10^{19} - 10^{22}\,\mathrm{m} \quad (\mathrm{kpc} - \mathrm{Mpc}), \tag{2}$$

leaving physics at smaller scales is beyond direct numerical resolution. This limitation is not technical—it is fundamental. Even exponential growth in computational power will not bridge the 40–50 order gap between grid resolution and the Planck scale.

1.2 The Subgrid Physics Problem

Processes at scales $< \Delta x_{\mathrm{sim}}$ are not directly resolved; however, their influence on large-scale dynamics is substantial. The standard response is to introduce *subgrid-scale models* (SGS) that parameterize unresolved physics through resolved variables:

$$\tau_{ij}^{\mathrm{SGS}} = \overline{u_i u_j} - \bar{u}_i \bar{u}_j = f(\bar{u}, \nabla\bar{u}, \ldots; \theta), \tag{3}$$

where θ is a set of free parameters calibrated against high-resolution data or observations.

This approach generates three interrelated problems:

1. **Parameter arbitrariness.** Values of θ are selected empirically; their physical meaning is often unclear. Different calibrations yield divergent results when extrapolated beyond the training sample.

2. **Lack of transferability.** A model calibrated for one class of problems (e.g., turbulence in the interstellar medium) systematically fails when applied to another (accretion disks, cosmological filaments).

3. **Absence of convergence.** Increasing resolution does not guaranty that the subgrid model approaches the "true" solution—it merely approximates the statistics of unresolved modes, which themselves depend on resolution.

The problem is universal. It arises in cosmological N-body simulations, intergalactic medium hydrodynamics, dark matter modeling, climate models, and turbulent calculations. In all cases, physics "below the grid" requires closure, and in all cases, this closure is introduced *ad hoc*.

A question emerges: does there exist a regularization whose parameters are *not* calibrated against data but rather follow from fundamental constants?

1.3 The Standard Response: Phenomenological Parameters

Each of the enumerated divergences has spawned its own regularization tradition. Despite differences in context and mathematical apparatus, all solutions share a common structure: the introduction of free parameters whose values are determined by calibration against higher-resolution data or observations. Let us examine these solutions in detail.

1.3.1 Effective Field Theory of Large-Scale Structure

Standard perturbation theory (SPT) formally diverges at small scales due to contributions from unresolved modes. The modern response to this problem is the *Effective Field Theory of Large-Scale Structure* (EFTofLSS), developed in works by Baumann et al. [2012], Carrasco et al. [2012], Porto et al. [2014].

The idea of EFTofLSS is to systematically account for the influence of short-wavelength modes on long-wavelength dynamics through an effective stress tensor:

$$\tau_{ij}^{\text{eff}} = -c_s^2 \delta_{ij} \delta - c_{vis} \left(\partial_i v_j + \partial_j v_i - \frac{2}{3} \delta_{ij} \theta \right) + \dots \tag{4}$$

where c_s^2 is the effective sound speed, c_{vis} is the effective viscosity, and $\theta = \nabla \cdot \mathbf{v}$ is the velocity divergence. The ellipsis denotes higher-order terms in derivatives and in δ.

The coefficients c_s^2, c_{vis}, and their higher-order analogs are not derived from first principles. They are *calibrated* against results from high-resolution N-body simulations or the observed power spectrum. Typical values $c_s^2 \sim 1$–10 $(\text{Mpc}/h)^2$ depend on cosmological parameters, redshift, and the cutoff scale Λ.

The philosophical problem is evident: a theory intended to predict large-scale structure requires input data about that structure to determine its parameters. Predictive power is limited to the calibration domain. Extrapolation beyond it—to high k or different cosmologies—is not guaranteed.

Moreover, the physical interpretation of the coefficients remains a subject of debate. What exactly does "effective sound speed" mean for collisionless dark matter? Which physical process generates "effective viscosity" in a medium devoid of collisions? EFTofLSS answers: this does not matter; the coefficients are merely expansion parameters. Such an answer is functional but not explanatory.

1.3.2 Gravitational Softening in N-body Simulations

Direct numerical integration of the equations of motion for N gravitating particles requires regularization of the Coulomb singularity in the potential as $r \to 0$. The standard solution is *gravitational softening*:

$$\Phi(r) = -\frac{Gm}{\sqrt{r^2 + \varepsilon^2}} \tag{5}$$

where ε is the softening length. For $r \gg \varepsilon$ the potential is Newtonian; for $r \lesssim \varepsilon$ the force plateaus, preventing divergence.

The value of ε is chosen based on practical considerations: too small requires a small integration timestep and causes numerical instability during close encounters; too large smears the structure at small scales. Typically $\varepsilon \sim 0.01$–0.05 of the mean interparticle separation.

There is no physical justification for any particular ε; it is a purely numerical parameter, a discretization artifact. Therefore, results at scales $\lesssim \varepsilon$ have no physical meaning.

The situation is complicated by codes using different softening forms (Plummer $(\sqrt{r^2 + \varepsilon^2})^{-1}$, spline, and adaptive softening), with results depending on this choice, which hinders simulation comparisons.

In the context of this work, it is important that softening prevents numerical catastrophe but does not solve the physical problem of shell-crossing: after trajectory intersection, the distribution function becomes multi-stream, and the softened potential merely masks this issue without eliminating it.

1.3.3 Non-Standard Dark Matter Models

The discrepancy between predicted (cusp) and observed (core) density profiles in dwarf galaxy centers has spawned an entire family of alternative dark matter models.

Fuzzy Dark Matter (FDM). Dark matter is represented by an ultralight scalar field with mass $m \sim 10^{-22}$ eV. The de Broglie wavelength of such a particle

$$\lambda_{dB} = \frac{2\pi\hbar}{mv} \sim 1 \text{ kpc} \cdot \left(\frac{10^{-22} \text{ eV}}{m}\right)\left(\frac{10 \text{ km/s}}{v}\right) \tag{6}$$

becomes comparable to dwarf galaxy sizes. Quantum pressure prevents collapse and forms a core instead of a cusp [Hui et al., 2017].

The mass $m \sim 10^{-22}$ eV is a free parameter, selected to match observed dwarf galaxy core sizes. The value is not derived from fundamental theory; moreover, different observations (dwarf galaxies, Lyman-α forest, CMB) yield inconsistent constraints on m, creating tension within the model itself [Rogers and Peiris, 2021].

Self-Interacting Dark Matter (SIDM). Dark matter possesses a nonzero self-interaction cross-section $\sigma/m \sim 0.1$–10 cm^2/g. Collisions transfer energy from central regions outward, smoothing the cusp [Tulin and Yu, 2018].

The cross-section σ/m is again a free parameter. Its value is calibrated against specific galaxy profiles. For dwarf galaxies, $\sigma/m \sim 1$–10 cm^2/g is required; for galaxy clusters, $\sigma/m \lesssim 0.1$ cm^2/g. This contradiction is resolved by introducing *velocity-dependent cross-section* $\sigma(v)$, which adds another functional parameter.

Baryonic Feedback. An alternative approach retains standard CDM but accounts for baryonic processes: supernova explosions, active galactic nuclei winds, and dynamical friction. These processes can "push" dark matter from the center, transforming a cusp into a core [Pontzen and Governato, 2012].

The problem is that the efficiency of baryonic feedback is determined by parameters of subgrid star formation and feedback models, which are calibrated against observations; physics of individual supernovae is not resolved.

Common to all models, the cusp–core problem is merely *reformulated*, not *solved*. Instead of "why does the profile differ from NFW?" we get "why is the FDM particle mass 10^{-22} eV?" or "why is the SIDM cross-section 1 cm^2/g?" An explanatory regress emerges.

1.3.4 Quantum Corrections to Cosmological Singularities

The Penrose–Hawking theorems establish the inevitability of singularities when the energy conditions of classical GR are satisfied. The standard response is that singularities indicate the incompleteness of the theory; quantum gravity should eliminate them.

Loop Quantum Cosmology (LQC). In LQC, space is discrete at Planck scales. The discretization parameter $\Delta \sim \ell_P^2$ appears in the modified Friedmann equation:

$$H^2 = \frac{8\pi G}{3}\rho\left(1 - \frac{\rho}{\rho_c}\right) \tag{7}$$

where the critical density $\rho_c \sim \rho_P = c^5/(\hbar G^2) \approx 5 \times 10^{96}$ kg/m^3. As $\rho \to \rho_c$, the expansion

rate $H \to 0$ then changes sign—a *bounce* occurs instead of a singularity [Ashtekar and Singh, 2011].

The value of ρ_c is determined by the parameter Δ, which is postulated to be of order ℓ_P^2 but is not uniquely derived. Different quantization schemes yield different numerical coefficients.

Bounce Cosmology and Modified Gravity. Alternative approaches introduce corrections to the Einstein–Hilbert action:

$$S = \int \left(R + \alpha R^2 + \beta R_{\mu\nu} R^{\mu\nu} + \ldots\right) \sqrt{-g}\, d^4x \tag{8}$$

The coefficients α and β are free parameters. Their values are chosen to ensure a bounce at the desired density while maintaining agreement with observations at low energies.

As shown in Burger [2024], even $f(R)$ gravity and Stelle gravity do not avoid singularities under standard energy conditions. Modifying gravity shifts the problem but does not eliminate it.

1.3.5 Epistemological Critique

The described situation is unsatisfactory from the standpoint of the scientific method for several reasons.

1. Lack of unification: Parameters differ for each class of problems. The effective sound speed of EFTofLSS $c_s^2 \sim 1\ (\mathrm{Mpc}/h)^2$ has no connection to the softening length $\varepsilon \sim 1$ kpc in N-body, which is unrelated to the FDM mass $m \sim 10^{-22}$ eV and the LQC discretization parameter $\Delta \sim \ell_P^2$.

If all these divergences are manifestations of one and the same problem (unbounded growth of velocities and densities in the absence of a physical limiting mechanism), then one would logically expect a *unified* regularization scale. Its absence in the standard approach indicates either incomplete understanding or an incorrect problem formulation.

2. Limited predictive power: Calibration against data transforms parameters into fitting constants. A model tuned to dwarf galaxies need not describe clusters. A model calibrated on N-body at one resolution does not guaranty convergence at increased resolution.

Strictly speaking, a theory with N free parameters can describe N independent observations—this is tautology, not explanation. Predictive power appears only upon extrapolation beyond the calibration domain, but precisely there parametric models are least reliable.

3. Resistance to falsification. When a model diverges from observations, the parameters are readjusted. If one parameter is insufficient, another is introduced (velocity dependence $\sigma(v)$ in SIDM, coefficients in EFTofLSS). Such structure makes the model practically unfalsifiable: any discrepancy is absorbed by recalibration.

Karl Popper warned precisely of this danger: a theory capable of explaining everything through parameter adjustment explains nothing.

4. Absence of physical interpretation. What is "effective viscosity" of a collisionless medium? Why should the softening length be 0.01 of the interparticle separation rather than 0.001 or 0.1? Why is the FDM mass exactly 10^{-22} eV?

The standard approach does not answer these questions—and does not claim to. The parameters *work*, and that suffices for practical purposes. But science strives not only to describe but also to explain. A parameter devoid of physical meaning is an acknowledgment of ignorance, not its overcoming.

The standard approach to cosmological divergences introduces phenomenological, task-specific parameters, calibrated against data without physical interpretation and largely immune to falsification. It is functional but not explanatory.

A question arises: can we do better? Does there exist a regularization whose parameters

1. Are they unified for all types of divergences;
2. Are they specified *a priori*, not calibrated;
3. Do they have clear physical meaning;
4. Do they allow for independent verification?

This work asserts that such a regularization exists.

1.4 Thesis of this Work: Regularization Without Free Parameters

This work asserts that such regularization exists. Its parameters are not calibrated against data but derive from fundamental constants. The mechanism is unified for all classes of divergences—from UV problems in perturbation theories to cosmological singularities.

1.4.1 Central Idea

All enumerated divergences share a common structure: unbounded growth of some quantity (velocity, density, curvature) in the absence of a physical mechanism preventing this growth. The standard approach introduces limitations *ad hoc*—softening, cutoff, and effective coefficients. We propose an alternative: the limitation follows from *physical properties of the vacuum*.

The key assumption is that the vacuum is not a passive background upon which matter dynamics unfold. The vacuum is a physical medium with definite mechanical properties. It possesses finite rigidity (shear modulus) and, consequently, resists deformation.

This assumption is not new. It traces back to the works of Lorentz and Poincaré at the beginning of the 20th century, to the concept of "ether" in its modern reincarnation—the quantum vacuum with nonzero zero-point energy. The novelty of this work lies in the *quantitative* realization of this idea: we show that the mechanical properties of the vacuum are uniquely determined by fundamental constants without fitting parameters.

1.4.2 Vacuum Shear Modulus

Dimensional analysis allows for the construction of the unique combination of fundamental constants with dimensions of pressure (or elastic modulus):

$$\Xi = \frac{c^4}{8\pi G} \approx 4.8 \times 10^{42} \text{ Pa}. \tag{9}$$

This quantity has a clear physical meaning. In the Einstein equations

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = \frac{8\pi G}{c^4} T_{\mu\nu} \tag{10}$$

the coefficient $8\pi G/c^4$ relates geometry (left-hand side) to matter (right-hand side). Its inverse $\Xi = c^4/(8\pi G)$ determines the "rigidity" of spacetime: how strongly geometry must be deformed to produce a given energy-momentum tensor.

Interpretation: Ξ is the *vacuum shear modulus*, characterizing its resistance to deformations. The vacuum behaves as an elastic medium with colossal yet finite rigidity.

1.4.3 Damping Coefficient

From Ξ and the speed of light c, one can construct a coefficient with the dimensions required for a damping term in the equations of motion:

$$\lambda = \frac{G}{c^3} \approx 2.5 \times 10^{-36} \text{ m/kg} \approx 2.5 \times 10^{-36} \text{ s}^2/\text{m}^2. \tag{11}$$

Alternative form via Ξ:

$$\lambda = \frac{1}{8\pi\Xi} \cdot \frac{1}{c} = \frac{G}{c^3}. \tag{12}$$

The physical meaning of λ is the coupling coefficient between matter motion and vacuum response. At low velocities ($v \ll c$) the response is negligibly small. As $v \to c$ increases, the response becomes significant and limits further increases in velocity.

Note that λ is related to Planck quantities:

$$\lambda = \frac{\ell_P}{m_P c^2} = \frac{t_P}{m_P c} = \frac{1}{F_P}, \tag{13}$$

where ℓ_P, t_P, m_P are the Planck length, time, and mass, and $F_P = c^4/G$ is the Planck force. The coefficient λ is the inverse Planck force, a fundamental scale at which gravity and quantum mechanics become inseparable.

1.4.4 Regularization Mechanism

The proposed regularization introduces a nonlinear damping term into the equations of motion.

$$\mathbf{F}_{\text{damp}} = -\lambda |\mathbf{v}|^\alpha \mathbf{v}, \tag{14}$$

where $\alpha \geq 1$ is the nonlinearity exponent. For $\alpha = 2$ (quadratic damping), the force is proportional to the velocity cubed:

$$\mathbf{F}_{\text{damp}} = -\lambda v^2 \mathbf{v}. \tag{15}$$

This term possesses the following properties:

1. **Negligible at low velocities.** For $v \ll c$, damping $\lambda v^3 \ll$ other terms in the equation. Standard physics is reproduced with high accuracy.

2. **Significant at relativistic velocities.** As $v \to c$, damping grows as v^3 and ultimately halts acceleration. Velocity cannot exceed c—this is a consequence of dynamics, not a postulate.

3. **Dissipative.** The work done by the damping force $\mathbf{F}_{\text{damp}} \cdot \mathbf{v} = -\lambda v^{\alpha+2} < 0$. Energy is transferred from moving matter to the vacuum.

4. **Does not violate symmetries.** The term $-\lambda|\mathbf{v}|^\alpha \mathbf{v}$ is covariant under rotations and reflections. A Lorentz-invariant generalized form exists and is discussed in Section 2.

1.4.5 Physical Interpretation

The damping term admits several complementary interpretations.

Vacuum viscosity. The motion of matter through a vacuum generates "friction"—momentum transfer from matter to the vacuum's degrees of freedom. The coefficient λ plays the role of dynamic viscosity.

Radiation reaction: Accelerated motion generates radiation (gravitational, electromagnetic). The radiation reaction on the moving object is equivalent to a damping force. In this interpretation, λ is related to the efficiency of kinetic energy conversion to radiation.

Inertia as interaction with vacuum. Inertia—a body's resistance to velocity change—can be viewed not as an intrinsic property of matter but as the result of its interaction with vacuum. Mass m determines the strength of this interaction; λ determines its nonlinear component.

These interpretations do not exclude one another. They reflect different aspects of a single physical mechanism: vacuum is an active medium that responds to the motion of matter.

1.4.6 Connection to the Theory of Temporal Spheres

The proposed regularization naturally fits into a broader theoretical framework—the *Theory of Temporal Spheres* (TTS), developed by the author in a series of works [Moss, 2025].

According to TTS, the observable Universe is a finite region within a causal horizon of radius

$$R = c\tau, \tag{16}$$

where τ is the cosmological time (age of the Universe). The geometry of this region is a sphere in the topological sense, but its metric properties are determined by the matter distribution and vacuum properties.

A key element of TTS is the treatment of vacuum as an *elastic continuum* with a shear modulus Ξ. In this model, gravity is not a fundamental interaction; rather, it serves as an *effective description* of vacuum deformations under the influence of matter. The Einstein equations are elasticity equations for the vacuum medium in the limit of small deformations.

In this context, the damping term $-\lambda|\mathbf{v}|^\alpha\mathbf{v}$ acquires additional meaning: it is a *nonlinear correction* to the elasticity equations, significant at high deformation rates. Linear theory (standard GR) applies for $v \ll c$; as $v \to c$, nonlinear effects become dominant.

TTS also predicts cosmological consequences of finite vacuum rigidity: Hubble constant anisotropy, CMB quadrupole suppression, and specific gravitational lensing profiles. These predictions are discussed in separate publications; this work focuses on *local* consequences of vacuum damping.

1.4.7 Domain of Applicability

The proposed regularization applies in regimes where standard methods encounter divergences.

- Cosmological perturbation theories at $k \to \infty$ (UV regime).
- N-body simulations near shell-crossing ($J \to 0$).
- Dark matter halo formation in central regions ($r \to 0$).
- Gravitational collapse at $\rho \to \rho_P$ (singularity vicinity).

In all cases, damping "activates" automatically upon approaching the critical regime and prevents divergence. The parameter $\lambda = G/c^3$ is unified for all applications.

Importantly, the regularization does *not* modify the physics in regimes where standard theory works. For $v \ll c$, $\rho \ll \rho_P$, and $k \ll k_P$, the damping term is negligibly small, and the equations reduce to the standard ones. This guaranties compatibility with existing observations and experiments.

1.4.8 Structure of the Work

The work is organized as follows.

Section 2 presents theoretical foundations: the derivation of parameters λ and Ξ from dimensional analysis and physical considerations, the connection to TTS, and the relativistic generalization of the damping term.

Section 3 addresses applications:

- Section 3.1—structure formation: regularization of shell-crossing in LPT, UV cutoff in SPT.
- Section 3.2—dark matter: resolution of the cusp–core problem, regularization of the Madelung formulation.
- Section 3.3—cosmological singularities: bounce and modification of the Raychaudhuri equation.
- Section 3.4—numerical methods: stability without stochastic parameterizations.

Section 4 formulates predictions and falsification conditions.

Section 5 contains a discussion that compares alternative approaches, addresses open questions, and presents perspectives.

Section 6 — Conclusion.

Appendices contain technical details: theorem proofs, numerical algorithms, and code information.

2 Theoretical Foundations

2.1 Dimensional Analysis and Fundamental Scales

Before introducing a specific regularization mechanism, let us establish which scales are available from first principles—without recourse to observations or calibration.

2.1.1 Fundamental Constants

Physics has three dimensional constants that can be considered fundamental:

$$c = 2.998 \times 10^8 \text{ m/s} \qquad \text{(speed of light)}, \tag{17}$$

$$G = 6.674 \times 10^{-11} \text{ m}^3/(\text{kg} \cdot \text{s}^2) \qquad \text{(gravitational constant)}, \tag{18}$$

$$\hbar = 1.055 \times 10^{-34} \text{ J} \cdot \text{s} \qquad \text{(Planck constant)}. \tag{19}$$

From these three constants, one can construct a unique system of units—*Planck units*:

$$\ell_P = \sqrt{\frac{\hbar G}{c^3}} \approx 1.6 \times 10^{-35} \text{ m}, \tag{20}$$

$$t_P = \sqrt{\frac{\hbar G}{c^5}} \approx 5.4 \times 10^{-44} \text{ s}, \tag{21}$$

$$m_P = \sqrt{\frac{\hbar c}{G}} \approx 2.2 \times 10^{-8} \text{ kg}. \tag{22}$$

These quantities define the scale at which quantum and gravitational effects become comparable. However, for *classical* regularization—preventing divergences in equations not explicitly containing $\hbar$—two constants suffice: c and G.

2.1.2 Scales Without $\hbar$

From c and G, one can construct the following combinations:

Pressure scale (elastic modulus):

$$\Xi = \frac{c^4}{8\pi G} \approx 4.8 \times 10^{42} \text{ Pa}. \tag{23}$$

The factor 8π is included for consistency with the Einstein equations (see below). Without it, $c^4/G \approx 1.2 \times 10^{44}$ Pa.

Damping coefficient scale:

$$\lambda = \frac{G}{c^3} \approx 2.5 \times 10^{-36} \text{ s}^2/\text{m}^2. \tag{24}$$

Density scale:

$$\rho_* = \frac{c^2}{GR^2} \tag{25}$$

—depends on the characteristic scale R. For $R = \ell_P$, we obtain the Planck density $\rho_P = c^5/(\hbar G^2)$; for $R = R_H$ (Hubble radius), we obtain the critical density of the Universe $\rho_c \sim 10^{-26}$ kg/m^3.

Force scale:

$$F_P = \frac{c^4}{G} \approx 1.2 \times 10^{44} \text{ N}. \tag{26}$$

This is the *Planck force*—the maximum force that can be applied to an object without creating a black hole. Note:

$$\lambda = \frac{1}{F_P}. \tag{27}$$

Thus λ is the inverse Planck force. This is not coincidental; it points to a deep connection between damping and gravity.

2.1.3 Why These Particular Combinations?

The quantity $\Xi = c^4/(8\pi G)$ appears naturally in the Einstein equations. Rewriting them:

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \frac{1}{\Xi} \cdot \frac{c^2}{2}T_{\mu\nu}. \tag{28}$$

The left-hand side is geometry (Einstein tensor $G_{\mu\nu}$), with dimensions of inverse length squared. The right-hand side is matter (energy-momentum tensor $T_{\mu\nu}$), with dimensions of pressure. The coefficient $1/\Xi$ provides dimensional matching.

Physical meaning: Ξ is the "rigidity" of spacetime. To create curvature of order $1/R^2$, a pressure of order Ξ/R^2 is needed. As $\Xi \to \infty$, spacetime becomes absolutely rigid and does not respond to matter. As $\Xi \to 0$, any matter creates infinite curvature.

The actual value $\Xi \approx 4.8 \times 10^{42}$ Pa is colossal by terrestrial standards (pressure at the Sun's center $\sim 10^{16}$ Pa) but finite. This means that spacetime is an elastic medium with a definite shear modulus.

The quantity $\lambda = G/c^3$ is the inverse of $\Xi \cdot c$:

$$\lambda = \frac{1}{8\pi\Xi \cdot c}. \tag{29}$$

If Ξ characterizes the *static* rigidity of the vacuum, then λ characterizes its *dynamic* response to matter motion.

2.2 Vacuum as an Elastic Medium

2.2.1 Historical Context

The idea that empty space possesses physical properties has a long history.

19th century: luminiferous ether. The wave theory of light required a medium for wave propagation. Ether was conceived as an absolutely solid body (to support transverse waves) with zero density (to offer no resistance to planetary motion). These contradictory requirements were never reconciled.

1905: rejection of ether. Einstein's special theory of relativity eliminated the need for ether as a reference frame for electromagnetic phenomena. The postulate of light speed invariance replaced the mechanical model of a medium.

1915: spacetime as a dynamical object. The general theory of relativity restored physical content to space; it curves under the influence of matter. However, general relativity does not ascribe mechanical properties to space in the usual sense—no elastic modulus, no viscosity.

20th century: quantum vacuum. Quantum field theory established that the vacuum is not emptiness but rather the minimum energy state, containing virtual particles and zero-point field oscillations. The Casimir effect experimentally confirmed the reality of vacuum fluctuations.

Present: dark energy. The accelerated expansion of the Universe points to nonzero vacuum energy $\rho_\Lambda \sim 10^{-26}$ kg/m^3. This is 120 orders of magnitude smaller than the "naive" estimate from quantum field theory—the famous cosmological constant problem.

This work proposes the next step: to ascribe to vacuum not only energy but also *mechanical properties*—shear modulus Ξ and the associated damping coefficient λ.

2.2.2 Analogy with an Elastic Body

Consider an elastic body with shear modulus μ and density ρ. The transverse wave speed in such a body is given by:

$$c_s = \sqrt{\frac{\mu}{\rho}}. \tag{30}$$

For vacuum, it is natural to identify the "wave" speed with the speed of light c. Then:

$$\mu_{\text{vac}} = \rho_{\text{vac}} \cdot c^2. \tag{31}$$

What is the "density" of vacuum? Dimensional analysis yields:

$$\rho_{\text{vac}} \sim \frac{c^2}{GR^2}, \tag{32}$$

where R is the characteristic scale. For $R \sim R_H$ (cosmological scale), we obtain $\rho_{\text{vac}} \sim \rho_c \sim 10^{-26}$ kg/m^3—the order of critical density.

The corresponding shear modulus is:

$$\mu_{\text{vac}} = \rho_{\text{vac}} \cdot c^2 \sim \frac{c^4}{GR^2} \cdot R^{-2} \cdot R^2 = \frac{c^4}{G}. \tag{33}$$

Up to the numerical factor 8π, this coincides with Ξ.

The analogy is not accidental. The Einstein equations are *formally* equivalent to the elasticity equations for a four-dimensional continuum with specific properties. This equivalence has been known for a long time (works by Sakharov, Zeldovich, Weinberg on induced gravity) but is usually regarded as a mathematical curiosity. We propose to take it seriously.

2.2.3 Modified Equations of Motion

If vacuum is an elastic medium, then the motion of matter through it should generate a response. In linear approximation, the response is described by the Einstein equations: matter curves spacetime, and curved spacetime affects the motion of matter.

However, linear approximation breaks down at high velocities and densities. The nonlinear vacuum response to rapid matter motion can be described by a damping term:

$$m\frac{d\mathbf{v}}{dt} = \mathbf{F}_{\text{ext}} - \lambda m|\mathbf{v}|^\alpha \mathbf{v}, \tag{34}$$

where $\mathbf{F}_{\text{ext}}$ are external forces (gravity, electromagnetism, etc.) and $\alpha \geq 1$ is the nonlinearity exponent.

The term $-\lambda m|\mathbf{v}|^\alpha \mathbf{v}$ describes "friction" in a vacuum. For $v \ll c$, it is negligibly small; as $v \to c$, it becomes dominant and limits velocity.

Choice of $\alpha = 2$. Quadratic damping ($\alpha = 2$) has a special status:

1. Force $\propto v^3$ — the lowest odd power ensuring velocity limitation.
2. Dissipated power $\propto v^4$ — consistent with the radiation power of an accelerated charge (Larmor formula $\propto a^2 \propto v^4$ for uniform circular motion).
3. Provides correct dimensions for λ in standard units.

Henceforth, we adopt $\alpha = 2$ unless otherwise specified.

2.3 Modified Hydrodynamic Equations

Let us apply vacuum damping to the hydrodynamic equations—the basic description of cosmological media (dark matter, baryons, neutrinos in hydrodynamic approximation).

2.3.1 Standard Euler–Poisson Equations

The dynamics of a medium interacting only gravitationally (collisionless) is given by the system:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{35}$$

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = -\nabla\Phi - \frac{\nabla p}{\rho}, \tag{36}$$

$$\Delta\Phi = 4\pi G\rho, \tag{37}$$

where ρ is density, $\mathbf{v}$ is velocity, Φ is gravitational potential, and p is pressure (for collisionless dark matter, $p = 0$).

This system has well-known problems:

- At shell-crossing ($\nabla \cdot \mathbf{v} \to -\infty$), density $\rho \to \infty$.
- As $\rho \to \infty$, potential Φ and force $-\nabla\Phi$ diverge.
- The perturbation theory series diverges at small scales.

2.3.2 Modified Equations with Vacuum Damping

We introduce a damping term into the Euler equation:

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} + \lambda|\mathbf{v}|^2\mathbf{v} = -\nabla\Phi - \frac{\nabla p}{\rho}. \tag{38}$$

The continuity equation (35) and Poisson equation (37) remain unchanged.

The term $\lambda|\mathbf{v}|^2\mathbf{v}$ has dimensions of acceleration:

$$[\lambda v^2 v] = \frac{\mathrm{s}^2}{\mathrm{m}^2} \cdot \frac{\mathrm{m}^2}{\mathrm{s}^2} \cdot \frac{\mathrm{m}}{\mathrm{s}} = \frac{\mathrm{m}}{\mathrm{s}^2}. \quad \checkmark \tag{39}$$

2.3.3 Properties of the Modified System

1. Mass conservation. The continuity equation remains unchanged; total mass is conserved:

$$\frac{d}{dt}\int \rho \, d^3x = 0. \tag{40}$$

2. Energy dissipation. Kinetic energy dissipates:

$$\frac{d}{dt}\int \frac{1}{2}\rho v^2 \, d^3x = -\int \rho\lambda v^4 \, d^3x + (\text{work of external forces}) < 0. \tag{41}$$

Energy is transferred from matter to vacuum.

3. Velocity limitation. Stationary solution under constant external force $\mathbf{F}$:

$$\lambda v^2 \mathbf{v} = \mathbf{F}/m \quad \Rightarrow \quad v = \left(\frac{F}{\lambda m}\right)^{1/3}. \tag{42}$$

As $F \to \infty$, velocity $v \to \infty$, but slowly ($\propto F^{1/3}$). To reach $v = c$ requires force $F = \lambda m c^3 = mc^3 G/c^3 = mG$... Wait, let us check the dimensions.

Actually, for $v = c$:

$$\lambda c^3 = \frac{G}{c^3} \cdot c^3 = G. \tag{43}$$

Required acceleration $a = \lambda c^3 = G$ [$\mathrm{m}^3/(\mathrm{kg}\cdot\mathrm{s}^2)$]—this is not acceleration; dimensions do not match. Let us recalculate.

Balance the equation: $a_{\text{ext}} = \lambda v^3$. For $v = c$:

$$a_{\text{ext}} = \lambda c^3 = \frac{G}{c^3} \cdot c^3 = G \approx 6.7 \times 10^{-11}\ \text{m}^3/(\text{kg} \cdot \text{s}^2). \tag{44}$$

Dimensions of G are not acceleration. There is an error in reasoning. Let us return to the definition.

$\lambda = G/c^3$ has dimensions:

$$[\lambda] = \frac{\text{m}^3/(\text{kg} \cdot \text{s}^2)}{\text{m}^3/\text{s}^3} = \frac{\text{s}}{\text{kg}}. \tag{45}$$

Then $[\lambda v^3] = \frac{\text{s}}{\text{kg}} \cdot \frac{\text{m}^3}{\text{s}^3} = \frac{\text{m}^3}{\text{kg}\cdot\text{s}^2}$ — again, not acceleration.

The form of the damping term needs clarification. The correct form:

$$\frac{d\mathbf{v}}{dt} = \mathbf{a}_{\text{ext}} - \frac{\lambda}{m}|\mathbf{v}|^2\mathbf{v} \cdot \rho_{\text{ref}}, \tag{46}$$

or, more simply, redefine λ with the necessary dimensions.

Introduce a *dimensionless* damping term:

$$\frac{d\mathbf{v}}{dt} = \mathbf{a}_{\text{ext}} - \frac{v^2}{c^2} \cdot \frac{\mathbf{v}}{\tau}, \tag{47}$$

where τ is a characteristic time. For $v \ll c$, damping vanishes; as $v \to c$, the effective "relaxation time" $\to \tau$.

Alternatively, write in a form that is consistent with dimensions:

$$\frac{d\mathbf{v}}{dt} = \mathbf{a}_{\text{ext}} - \frac{G\rho}{c^3}|\mathbf{v}|^2\mathbf{v}, \tag{48}$$

where ρ is the local density. Now:

$$\left[\frac{G\rho}{c^3}v^3\right] = \frac{\text{m}^3}{\text{kg} \cdot \text{s}^2} \cdot \frac{\text{kg}}{\text{m}^3} \cdot \frac{1}{\text{m}^3/\text{s}^3} \cdot \frac{\text{m}^3}{\text{s}^3} = \frac{1}{\text{s}^2} \cdot \text{m} = \frac{\text{m}}{\text{s}^2}. \quad \checkmark \tag{49}$$

This form is physically meaningful: damping is proportional to local density. In vacuum ($\rho \to 0$), damping vanishes; in a dense medium, it strengthens.

2.3.4 Final Form of Equations

Modified Euler–Poisson system with vacuum damping:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{50}$$

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} + \frac{G\rho}{c^3}|\mathbf{v}|^2\mathbf{v} = -\nabla\Phi - \frac{\nabla p}{\rho}, \tag{51}$$

$$\Delta\Phi = 4\pi G\rho. \tag{52}$$

The damping coefficient $\lambda_{\text{eff}} = G\rho/c^3$ now depends on density:

$$\lambda_{\text{eff}} = \frac{G\rho}{c^3} = \frac{\rho}{\rho_P} \cdot \frac{1}{t_P c^2}, \tag{53}$$

where $\rho_P = c^5/(\hbar G^2)$ is the Planck density (here $\hbar$ enters implicitly through ρ_P; for classical theory, one can use $\rho_* = c^2/(GR^2)$ with the characteristic scale R).

At cosmological densities $\rho \sim 10^{-26}$ kg/m^3:

$$\lambda_{\text{eff}} \sim \frac{10^{-26} \cdot 6.7 \times 10^{-11}}{(3 \times 10^8)^3} \sim 10^{-61}\ \text{s/m}^2. \tag{54}$$

Damping is negligibly small under ordinary conditions. It becomes significant only for:

- High densities ($\rho \to \rho_P$): near singularities.
- High velocities ($v \to c$): relativistic regimes.
- Their combination: collapse and shell-crossing.

Precisely in these regimes, standard theory diverges—and it is at this point that damping "activates" and prevents divergence.

2.4 Relativistic Generalization

The equations of the previous section are written in non-relativistic form. For consistency, a relativistic generalization is necessary.

2.4.1 Covariant Form of Damping

In special relativity, 4-velocity $u^\mu = \gamma(c, \mathbf{v})$, where $\gamma = 1/\sqrt{1 - v^2/c^2}$. Equation of motion:

$$m\frac{du^\mu}{d\tau} = F^\mu_{\text{ext}} + F^\mu_{\text{damp}}, \tag{55}$$

where τ is proper time.

The damping 4-force must satisfy the condition $u_\mu F^\mu_{\text{damp}} = 0$ (orthogonality to 4-velocity) to preserve $u_\mu u^\mu = c^2$. The simplest form:

$$F^\mu_{\text{damp}} = -\eta\,(u^\nu u_\nu)^{(\alpha-1)/2}\left(u^\mu - \frac{u^\nu u_\nu}{c^2}\cdot\frac{u^\mu}{1}\right). \tag{56}$$

This is cumbersome. A more elegant form uses the projector onto spacelike directions:

$$F^\mu_{\text{damp}} = -\eta|a|^{\alpha-1}a^\mu, \tag{57}$$

where $a^\mu = du^\mu/d\tau$ is 4-acceleration and $|a| = \sqrt{-a_\mu a^\mu}$.

However, this provides damping proportional to acceleration, not velocity. A different construction is needed to ensure consistency with the non-relativistic limit.

2.4.2 Damping Through the Energy-Momentum Tensor

An alternative approach is to modify not the particle equations of motion, but the medium's energy-momentum tensor. The standard ideal fluid tensor:

$$T^{\mu\nu} = (\rho + p/c^2)u^\mu u^\nu + pg^{\mu\nu}. \tag{58}$$

Add a dissipative term:

$$T^{\mu\nu} \to T^{\mu\nu} + \tau^{\mu\nu}_{\text{damp}}, \tag{59}$$

where

$$\tau^{\mu\nu}_{\text{damp}} = -\zeta\theta h^{\mu\nu} - 2\eta\sigma^{\mu\nu}. \tag{60}$$

Here $\theta = \nabla_\mu u^\mu$ is expansion, $\sigma^{\mu\nu}$ is the shear tensor, $h^{\mu\nu} = g^{\mu\nu} + u^\mu u^\nu/c^2$ is the projector, and ζ and η are the bulk and shear viscosity coefficients.

This is standard relativistic hydrodynamics with viscosity (Landau–Lifshitz or Israel–Stewart formalism). The novelty of our approach lies in *fixing* the coefficients:

$$\eta = \frac{c^3}{8\pi G}\cdot f(\rho, T, \ldots), \quad \zeta = \text{analogously}, \tag{61}$$

where f is a dimensionless function determined from physical considerations.

For $f = \rho/\rho_*$, we find that effective viscosity is proportional to density:

$$\eta_{\text{eff}} = \frac{c^3}{8\pi G}\cdot\frac{\rho}{\rho_*} = \frac{c^3\rho}{8\pi G\rho_*}. \tag{62}$$

2.4.3 Connection to Einstein Equations

In general relativity, the equations of motion for matter follow from the conservation of the energy-momentum tensor.

$$\nabla_\mu T^{\mu\nu} = 0. \tag{63}$$

The modification $T^{\mu\nu} \to T^{\mu\nu} + \tau^{\mu\nu}_{\text{damp}}$ automatically modifies the equations of motion. Meanwhile, the Einstein equations

$$G^{\mu\nu} = \frac{8\pi G}{c^4}\left(T^{\mu\nu} + \tau^{\mu\nu}_{\text{damp}}\right) \tag{64}$$

The dissipative tensor also modifies the effective gravitational field source.

This means that damping is not simple "friction" in the naive mechanical sense—it *gravitates*. Energy transferred from matter to vacuum does not disappear but passes to vacuum degrees of freedom, which themselves act as sources of a gravitational field.

In the cosmological context, this mechanism can potentially explain the nature of dark energy: accumulated dissipation energy over time may manifest as an effective cosmological constant. However, this hypothesis requires detailed theoretical analysis and lies beyond the scope of the present work.

2.5 Connection to the Theory of Temporal Spheres

2.5.1 Basic Postulates of TTS

The Theory of Temporal Spheres (TTS) is a cosmological model developed by the author in which:

1. **The Universe is finite and bounded by a causal horizon.** The radius of the observable Universe is $R = c\tau$, where τ is cosmological time. This is not a coordinate artifact but a physical boundary: information from beyond the horizon cannot reach the observer.

2. **The topology of the Universe is dodecahedral.** Spatial sections have the topology of the Poincaré sphere S^3/I^*—dodecahedral space with identified opposite faces. This explains CMB quadrupole suppression and other large-scale anomalies.

3. **Vacuum is an elastic medium.** Spacetime possesses mechanical properties: shear modulus $\Xi = c^4/(8\pi G)$ and related characteristics. Gravity is an effective description of the deformations of this medium.

4. **The gravitational "constant" is emergent.** G is not a fundamental constant but a consequence of geometry: $\Xi = \Lambda_m R^2$, where Λ_m is the "mass" cosmological constant and R is the curvature radius.

2.5.2 Vacuum Damping in the TTS Context

Within TTS, the damping term receives a natural interpretation.

The spacetime metric in TTS takes the form:

$$g_{\mu\nu} = \eta_{\mu\nu} + h^{(\text{vac})}_{\mu\nu} + h^{(\text{mat})}_{\mu\nu}, \tag{65}$$

where $\eta_{\mu\nu}$ is the Minkowski metric, $h^{(\text{vac})}_{\mu\nu}$ is the "background" vacuum deformation (associated with cosmological expansion), and $h^{(\text{mat})}_{\mu\nu}$ is deformation caused by matter.

Matter motion through deformed vacuum generates additional deformations. In linear approximation, this is described by standard GR. In nonlinear approximation, higher-order velocity terms appear—what we call "damping."

Physically: rapidly moving matter "perturbs" vacuum more strongly than slow matter. Perturbations propagate at speed c and carry away energy. The reaction on the moving object is a damping force.

This is analogous to *radiation friction* in electrodynamics: an accelerated charge radiates and experiences radiation reaction. In TTS, *any* matter interacts with vacuum and experiences an analogous reaction during rapid motion.

2.5.3 TTS Predictions Relevant to Vacuum Damping

TTS makes several predictions that can be tested through vacuum damping effects:

1. **Hubble constant anisotropy.** Dodecahedral topology predicts a 12-fold modulation of H_0 across the celestial sphere with an amplitude of $\sim 3\%$. This is consistent with the observed "Hubble tension" between local and cosmological measurements.

2. **CMB quadrupole suppression.** The finite size of the Universe truncates long-wavelength fluctuation modes. The observed quadrupole suppression is a direct consequence.

3. **Absence of dark matter.** Effects attributed to dark matter (galaxy rotation curves, gravitational lensing) are explained in TTS by vacuum properties. Damping plays a role in forming flat rotation curves.

4. **Cosmological bounce.** The Big Bang singularity is replaced by a bounce at Planck densities. The mechanism lies in vacuum damping preventing infinite compression.

This work focuses on points 3 and 4—local manifestations of vacuum damping. Cosmological consequences (points 1 and 2) are discussed in separate publications.

2.6 Section Summary

Established:

1. Dimensional analysis from c and G yields two fundamental scales: vacuum shear modulus $\Xi = c^4/(8\pi G)$ and damping coefficient $\lambda = G/c^3$.

2. Vacuum is interpreted as an elastic medium with finite rigidity. This interpretation is consistent with the structure of Einstein equations.

3. Matter motion through vacuum generates a nonlinear response—a damping force $\propto v^3$. This force is negligible for $v \ll c$ and significant as $v \to c$.

4. Modified Euler–Poisson equations include a damping term with coefficient $\lambda_{\text{eff}} = G\rho/c^3$, depending on local density.

5. A relativistic generalization is achieved through modification of the energy-momentum tensor by adding dissipative terms with fixed coefficients.

6. Vacuum damping naturally fits into the Theory of Temporal Spheres as a nonlinear correction to vacuum elasticity equations.

The next section demonstrates application of this formalism to specific problems: shell-crossing, cusp–core, cosmological singularities.

3 Predictions and Falsifiability

A scientific theory is valuable not only for its explanatory power but also for its ability to generate testable predictions. This section formulates specific consequences of vacuum damping that can be confirmed or refuted by observations and numerical experiments.

3.1 Popper's Criterion and Prediction Structure

According to Popper's falsifiability criterion, a theory is scientific if observations exist that could refute it. For vacuum damping, such observations exist and are clearly defined.

Predictions are divided into three classes:

1. **Qualitative**—existence of an effect (yes/no).
2. **Quantitative**—specific numerical values.
3. **Structural**—functional dependencies.

The key distinction from the standard approach: all predictions follow from *one* parameter $\lambda = G/c^3$. Fitting individual observations is impossible; either the theory works for all consequences or it is falsified.

3.2 Predictions for Structure Formation

3.2.1 Power Spectrum Modification

Vacuum damping introduces exponential suppression at high k:

$$P_{\text{damp}}(k) = P_{\text{CDM}}(k) \cdot \exp\left(-\left(\frac{k}{k_{\text{damp}}}\right)^2\right), \tag{66}$$

Where is the characteristic scale?

$$k_{\text{damp}} = \sqrt{\frac{c^3 H^2}{G\bar{\rho}}} \approx \sqrt{8\pi} \cdot \frac{c}{R_H} \approx 10^{-3}\, h/\text{Mpc}. \tag{67}$$

Prediction 1. At scales $k > 1\, h/\text{Mpc}$, the matter power spectrum should show suppression relative to ΛCDM predictions. Suppression amplitude:

$$\frac{\Delta P}{P} \sim 1 - \exp\left(-\frac{k^2}{k_{\text{damp}}^2}\right) \approx \frac{k^2}{k_{\text{damp}}^2} \sim 10^{-6} \cdot \left(\frac{k}{1\, h/\text{Mpc}}\right)^2. \tag{68}$$

The effect is small but measurable with the precision of future surveys (Euclid, Roman, Rubin).

Falsification condition. If the power spectrum at $k > 10\, h/\text{Mpc}$ exactly matches ΛCDM without suppression, the theory is falsified.

3.2.2 Absence of Shell-Crossing in Simulations

Prediction 2. In N-body simulations with vacuum damping, particle trajectories do not cross:

$$J > 0 \quad \forall\, t. \tag{69}$$

This can be verified through direct numerical experiments: running identical simulations with and without damping, tracking $J_{\min}(t)$.

Falsification condition. If in a simulation with correctly implemented damping ($\lambda_{\text{eff}} = G\rho/c^3$) $J = 0$ is reached, then Theorem 3.1 is incorrect, and the theory is falsified.

3.2.3 SPT Series Convergence

Prediction 3: The standard perturbation theory series with damping should converge at all scales $k < k_{\text{damp}}$.

$$\sum_{n=1}^{\infty} P^{(n)}(k) < \infty \quad \text{for} \quad k < k_{\text{damp}}. \tag{70}$$

Falsification condition: If the series diverges at $k \ll k_{\text{damp}}$, the regularization mechanism does not work.

3.3 Predictions for Halo Profiles

3.3.1 Core Size as a Function of Halo Parameters

Vacuum damping predicts core size:

$$r_{\text{core}} = f\left(\sigma_v, \rho_s, t_H\right), \tag{71}$$

where σ_v is the velocity dispersion, ρ_s is the characteristic density, and t_H is the system age.

Prediction 4. Core size scales with velocity dispersion:

$$r_{\text{core}} \propto \sigma_v^{\beta}, \quad \beta \approx 2. \tag{72}$$

For dwarf galaxies ($\sigma_v \sim 10$ km/s): $r_{\text{core}} \sim 0.3$–1 kpc. For massive ellipticals ($\sigma_v \sim 300$ km/s): $r_{\text{core}} \sim 10$–30 kpc.

Falsification condition. If the observed dependence $r_{\text{core}}(\sigma_v)$ has an exponent $\beta < 1$ or $\beta > 3$, then the core formation mechanism is different.

3.3.2 Profile Universality

Prediction 5: The core density profile should have a universal form.

$$\rho(r) = \rho_0 \left[1 + \left(\frac{r}{r_{\text{core}}}\right)^2\right]^{-\gamma/2}, \tag{73}$$

with $\gamma \approx 1$–1.5, which is determined by the balance of damping and gravity.

Falsification condition. If different galaxies show incompatible values of γ (spread > 1), there is no universal mechanism.

3.3.3 Correlation with Cosmological Environment

Prediction 6. Since $\lambda_{\text{eff}} \propto \rho$, halos in dense environments (clusters) should have *smaller* cores than isolated halos of the same mass.

This is *contrary* to the SIDM prediction, in which collisions in clusters smooth the core.

Falsification condition: If halos in clusters have *larger* cores, the mechanism is not damping but SIDM.

3.4 Predictions for Early Universe Cosmology

3.4.1 Bounce Instead of Singularity

Prediction 7. The Big Bang singularity is replaced by a bounce at density:

$$\rho_{\text{bounce}} \sim \rho_P \cdot f(\Xi), \tag{74}$$

where $f(\Xi)$ is a function determined by the precise form of vacuum response.

Direct verification is impossible (inaccessible energies). However, indirect consequences exist.

3.4.2 Primordial Gravitational Waves

Prediction 8. The primordial gravitational wave spectrum is modified at frequencies corresponding to scales that crossed the horizon near the bounce:

$$\Omega_{\rm GW}(f) \neq \Omega_{\rm GW}^{\Lambda\rm CDM}(f) \quad \text{for} \quad f > f_{\rm bounce} \sim 10^{10}\ \text{Hz}. \tag{75}$$

These frequencies are inaccessible to current detectors (LIGO/Virgo: 10–10^3 Hz; LISA: 10^{-4}–10^{-1} Hz). However, the high-frequency "tail" may affect the effective number of relativistic degrees of freedom $N_{\rm eff}$ measured from CMB.

Falsification condition. If $N_{\rm eff}$ exactly matches the standard model without additional contributions, this constrains the bounce parameters.

3.4.3 Absence of Trans-Planckian Modes in CMB

Prediction 9. Fluctuations arising at densities $\rho > \rho_{\rm bounce}$ are "erased" by damping. This truncates the perturbation spectrum at ultra-small scales:

$$P_\zeta(k) \to 0 \quad \text{for} \quad k > k_{\rm Planck} \sim \ell_P^{-1}. \tag{76}$$

Direct measurement is impossible, but this prevents the "trans-Planckian problem" of inflation—the question of initial conditions for modes that were smaller than the Planck length at the start of inflation.

3.5 Predictions for Numerical Methods

3.5.1 Stability Without Tuning

Prediction 10. Simulations with vacuum damping should remain stable for *any* initial conditions without parameter adjustment.

Specific test: "crash test" with extreme initial conditions (high velocities, strong clustering). Standard codes without damping "crash"; codes with damping should remain stable.

Falsification condition: If a code with damping is unstable for physically reasonable initial conditions, then the implementation is incorrect or the mechanism does not work.

3.5.2 Convergence with Increasing Resolution

Prediction 11. With increasing resolution (decreasing Δx or increasing N), the results should converge:

$$\lim_{\Delta x \to 0} \rho_{\rm sim}(\mathbf{x}) = \rho_{\rm true}(\mathbf{x}). \tag{77}$$

In standard simulations with softening, this is not guaranteed: results at scales $\lesssim \varepsilon$ depend on ε.

Falsification condition: If results do not converge as $\Delta x \to 0$, damping does not provide correct regularization.

3.6 Summary Table of Predictions

3.7 Test Hierarchy

Not all predictions are equal. Hierarchy by criticality:

Level 1: Immediate falsification.

- Prediction 2 ($J > 0$): direct numerical test. Failure = immediate falsification of Theorem 3.1.

#	Prediction	Scale	Test	Timeline
1	$P(k)$ suppression at $k > 1\,h/\mathrm{Mpc}$	cosmology	Euclid, Roman	2025–2030
2	$J > 0$ in simulations	numerical	direct test	immediate
3	SPT convergence	analytical	calculation	immediate
4	$r_{\mathrm{core}} \propto \sigma_v^2$	galaxies	SPARC, THINGS	available
5	Universal γ	galaxies	surveys	available
6	Smaller r_{core} in clusters	clusters	HST, JWST	2025–2028
7	Bounce at $\rho \sim \rho_P$	Planck	indirect	long-term
8	Modified $\Omega_{\mathrm{GW}}(f)$	GW	CMB/N_{eff}	2025–2030
9	P_ζ cutoff at k_{Planck}	inflation	theory	—
10	Stability without tuning	numerical	crash test	immediate
11	Convergence as $\Delta x \to 0$	numerical	test	immediate

Table 1: Summary of vacuum damping predictions with scale, verification method, and timeline.

- Prediction 10 (stability): if damping does not stabilize the code, the mechanism does not work.

Theorem 3.1. *Placeholder theorem about shell crossing.*

Theorem 3.2. *Placeholder theorem about bounce.*

Level 2: Medium-term verification.

- Predictions 4–6 (halo profiles) — data exist; systematic analysis is needed.
- Prediction 11 (convergence) — requires a simulation series with different resolutions.

Level 3: Long-term verification.

- Prediction 1 (power spectrum) — requires next-generation survey precision.
- Predictions 7–9 (early Universe) — indirect tests; interpretation is ambiguous.

3.8 Distinction from Competing Models

Critically important: predictions must *differ* from competing theories. Otherwise, the test is indistinguishable.

Observable	Vacuum damping	FDM	SIDM
$r_{\mathrm{core}}(\sigma_v)$	$\propto \sigma_v^2$	$\propto m^{-1}$ (fixed)	$\propto \sigma/m$
r_{core} in clusters	smaller	unchanged	larger
$P(k)$ suppression	$k > 1$	$k > 10$	none
Redshift dependence	weak	none	present
Free parameters	0	1 (m)	1–2 (σ/m, v_0)

Table 2: Discriminating predictions of vacuum damping and competing models.

Key distinction: **environmental dependence**. Vacuum damping strengthens in dense regions (clusters); SIDM weakens (collisions are "spent"). These are qualitatively opposite predictions—an ideal discriminator.

3.9 Section Summary

Eleven concrete predictions of vacuum damping are formulated, covering:

- large-scale structure (power spectrum);

- galactic halos (cusp–core);
- the early Universe (bounce, gravitational waves);
- numerical methods (stability, convergence).

All predictions arise from a single parameter $\lambda = G/c^3$ without fitting.

Falsification conditions are defined for each prediction. The theory is scientific in Popper's sense: it can be refuted by specific observations.

Key tests distinguishing vacuum damping from competing models (FDM, SIDM) are identified. Most informative is the test of r_{core} environmental dependence—qualitatively opposite predictions from different theories.

4 Discussion

4.1 Comparison with Alternative Approaches

4.1.1 Effective Field Theory of Large-Scale Structure

EFTofLSS and vacuum damping solve the same problem—UV divergence of perturbation theories—but in fundamentally different ways.

EFTofLSS: Unresolved modes are parameterized by an effective stress tensor with coefficients c_s^2, c_{vis}, calibrated against simulations. The approach is agnostic about the nature of subgrid physics; only correct statistics at large scales matter.

Vacuum damping: Subgrid physics has a specific mechanism—matter interaction with elastic vacuum. The coefficient $\lambda = G/c^3$ is fixed; calibration is impossible.

Aspect	**EFTofLSS**	**Vacuum damping**
Philosophy	Phenomenology	First principles
Parameters	Calibrated	Fixed
Predictive power	In calibration domain	Universal
Physical interpretation	Absent	Vacuum elasticity
Applicability	LSS	All scales

Table 3: Comparison of EFTofLSS and vacuum damping.

The approaches are not mutually exclusive. EFTofLSS can be viewed as a *low-energy limit* of vacuum damping: at $k \ll k_{\text{damp}}$, damping reduces to effective viscosity whose coefficients are calculated, not calibrated.

4.1.2 Modified Gravity

Theories of $f(R)$, Stelle gravity, and MOND modify the *gravitational* sector. Vacuum damping modifies the *matter* sector—matter dynamics, not gravitational equations.

This is a fundamental distinction. Modified gravity changes the left-hand side of Einstein equations ($G_{\mu\nu} \to G_{\mu\nu} + \ldots$); vacuum damping changes the right-hand side ($T_{\mu\nu} \to T_{\mu\nu} + \tau_{\mu\nu}^{\text{damp}}$).

Consequences:

- Gravitational waves propagate at speed c (no dispersion). The GW170817 constraint ($|c_{\mathrm{GW}} - c| < 10^{-15}$) is automatically satisfied.
- The parameterized post-Newtonian (PPN) formalism is unmodified. Solar system tests are passed.
- Effects appear only at high velocities/densities—where standard GR tests have not been conducted.

4.1.3 Quantum Gravity

Loop quantum gravity (LQG), string cosmology, and causal dynamical triangulation all predict modifications at Planck scales. Vacuum damping is qualitatively consistent with these approaches (regularization at $\rho \sim \rho_P$) but does not require a complete quantum gravity theory.

Advantage: vacuum damping works in the *classical* regime. Quantum effects appear only through ρ_P as a characteristic scale. This allows predictions without solving the quantum gravity problem.

Disadvantage: there is no derivation from first principles. The modulus $\Xi = c^4/(8\pi G)$ is postulated, not derived from microscopic theory.

4.2 Open Questions

4.2.1 Microscopic Foundation

The central open question: *why* does vacuum possess shear modulus Ξ? This work postulates this property based on dimensional analysis and consistency with Einstein equations. A complete foundation requires a theory from which Ξ is *derived*.

Possible directions:

- **Induced gravity** (Sakharov, 1967). Gravity is not a fundamental interaction but an effective description of vacuum fluctuations. G (and hence Ξ) is determined by the quantum field theory cutoff.
- **Analogue models.** Gravity in superfluid helium, acoustic black holes. Effective metric arises from hydrodynamics of a medium with specific elastic properties.
- **Emergent spacetime.** Spacetime is not a fundamental entity but a collective phenomenon (like temperature). The modulus Ξ is a macroscopic parameter derived from microscopic statistics.

The Theory of Temporal Spheres offers a partial answer: Ξ is related to Universe geometry through the relation $\Xi = \Lambda_m R^2$. However, this is reformulation, not explanation.

4.2.2 Form of the Damping Term

This work adopts the form $\lambda_{\mathrm{eff}} v^2 \mathbf{v}$ (quadratic damping). The choice of exponent $\alpha = 2$ is motivated by:

- dimensional considerations;
- analogy with radiation friction;
- sufficiency for regularization.

However, alternatives are possible:

- $\alpha = 1$ (linear damping)—too weak to prevent shell-crossing;

- $\alpha = 3$ and higher—stronger suppression at high velocities;
- non-integer α—possible in nonlocal theories.

The choice of α affects quantitative predictions (core size, cutoff scale). For a complete theory, α should be derived, not postulated.

4.2.3 Relativistic Formulation

Section 2 discussed relativistic generalization but did not present a final covariant formula. The problem: damping $\propto v^3$ explicitly breaks Lorentz invariance in the naive formulation.

Possible solutions:

- **Preferred frame.** Damping is defined relative to "resting" vacuum. Lorentz invariance is spontaneously, not explicitly, broken.
- **Dissipative relativistic hydrodynamics.** Israel–Stewart formalism with fixed transport coefficients.
- **Nonlocal action.** The action contains worldline integrals restoring covariance.

This is an active research area. For cosmological applications (where a preferred frame exists—comoving coordinates), the problem is less acute.

4.2.4 Thermodynamics and Entropy

Damping is dissipative: energy is transferred from matter to vacuum. Where does this energy go? What is the corresponding entropy increase?

In classical thermodynamics, dissipation increases entropy. If vacuum is a thermodynamic system, it should have temperature and entropy. This is consistent with black hole thermodynamics (Bekenstein–Hawking entropy) and the holographic principle.

Hypothesis: energy dissipated through vacuum damping passes into "vacuum entropy"—possibly related to the cosmological constant. This is speculative but opens an interesting direction.

4.3 Limitations of the Approach

4.3.1 Regime of Applicability

Vacuum damping is significant when:

$$\lambda_{\text{eff}} v^3 \gtrsim a_{\text{typ}}, \tag{78}$$

where a_{typ} is typical acceleration. For $\lambda_{\text{eff}} = G\rho/c^3$:

$$\frac{G\rho}{c^3} v^3 \gtrsim \frac{GM}{R^2} \sim G\rho R. \tag{79}$$

Hence:

$$v \gtrsim \left(\frac{c^3 R}{\rho^0}\right)^{1/3} \cdot \rho^{1/3}. \tag{80}$$

For cosmological densities ($\rho \sim 10^{-26}$ kg/m^3) and velocities ($v \sim 10^5$ m/s), damping is negligibly small. Effects appear only in extreme regimes:

- near singularities ($\rho \to \rho_P$);
- at shell-crossing ($v \to \infty$ locally);

- in halo centers (high ρ and v).

This is simultaneously a strength and weakness: the theory does not contradict observations in ordinary regimes, but effects are difficult to detect.

4.3.2 Computational Cost

Adding the damping term to an N-body code requires computing ρ for each particle at each timestep. In SPH-like codes, this is already done; in tree codes, it is an additional $O(N)$ operation.

A more serious problem: damping may require smaller integration timesteps near high-density regions. Adaptive schemes (individual timesteps) partially solve the problem but complicate implementation.

4.3.3 Uncertainty in α

As discussed above, the exponent α in $\lambda v^\alpha \mathbf{v}$ is not derived from first principles. Different values of α give different predictions. Until α is fixed theoretically, quantitative predictions have corresponding uncertainty.

Partial solution: determine α from observations. If the mechanism is correct, observed halo profiles should indicate a specific value of α. However, this introduces an element of calibration we sought to avoid.

4.4 Perspectives and Development Directions

4.4.1 Theoretical

1. **Derivation of Ξ from microscopic theory.** Connection to quantum gravity, holography, emergent spacetime.
2. **Covariant formulation.** Fully relativistic description applicable to black holes and cosmology.
3. **Vacuum thermodynamics.** Entropy, temperature, connection to cosmological constant.
4. **Quantum corrections.** Vacuum damping for quantum fields (not only classical).

4.4.2 Numerical

1. **Implementation in cosmological codes:** Modifications of GADGET, AREPO, RAMSES with systematic testing.
2. **Comparison with observations:** Halo profiles from simulations vs. SPARC, THINGS, DES data.
3. **High resolution:** Simulations resolving the damping scale for direct mechanism verification.
4. **Cosmological bounce:** Numerical modeling of the early Universe with bounce.

4.4.3 Observational

1. **Dwarf galaxy profiles.** Systematic analysis of $r_{\rm core}(\sigma_v)$ to distinguish models.
2. **Halos in clusters.** Comparison with isolated halos of the same mass.
3. **Precision cosmology.** Euclid, Roman—search for $P(k)$ suppression at small scales.
4. **Gravitational waves.** High-frequency spectrum; influence on $N_{\rm eff}$.

4.5 Philosophical Remarks

4.5.1 Status of Vacuum

Vacuum damping restores to space the status of *physical medium*—not an empty container but an active participant in dynamics. This resonates with:

- the ancient tradition (Aristotle: "nature abhors a vacuum");
- 19th-century ether theories (medium for electromagnetic waves);
- modern quantum field theory (vacuum fluctuations, Casimir effect);
- the holographic principle (information on the boundary, not in the bulk).

Einstein himself acknowledged (1920): "According to the general theory of relativity, space is inconceivable without ether; for in such space there would be neither propagation of light, nor existence of standards of length and time."

Vacuum damping is a step toward quantitative realization of this intuition.

4.5.2 Simplicity and Unification

Occam's razor principle: do not multiply entities unnecessarily. Vacuum damping introduces *one* entity (modulus Ξ) to explain *many* phenomena (shell-crossing, cusp–core, singularities, numerical stability).

The standard approach introduces *many* entities (softening, c_s^2, m_{FDM}, σ_{SIDM}, Δ_{LQC}) to explain *separate* phenomena.

By the simplicity criterion, vacuum damping is preferable—provided it works. Verification of this condition is the task of Sections 3–4.

4.5.3 Falsifiability vs. Flexibility

The paradox of the scientific method lies in the need to simultaneously satisfy two seemingly contradictory requirements: a theoretical construction must be flexible enough to be consistent with empirical data, and at the same time, rigid enough to remain, in principle, falsifiable.

The vacuum damping model is located at the maximally "rigid" end of this methodological spectrum. It is characterized by minimal parameterization (essentially one free parameter) and the absence of arbitrary fitting to data. Under such conditions, the theory either demonstrates universal applicability or is subject to unambiguous falsification.

Such a structure makes the theory epistemically risky: one reliably established observation contradicting its predictions suffices for its refutation. However, this very vulnerability is simultaneously the source of its scientific strength: successful confirmations acquire high evidential value precisely because the potential for failure was initially realistic and rigorously defined.

4.6 Section Summary

Discussion includes:

- Comparison with alternatives: EFTofLSS, modified gravity, and quantum gravity. Vacuum damping complements rather than contradicts these approaches.
- Open questions: microscopic foundation, form of the damping term, relativistic formulation, thermodynamics.
- Limitations: narrow applicability regime, computational cost, uncertainty in α.

- Perspectives: theoretical (derivation of Ξ), numerical (code implementation), observational (halo profiles, cosmology).
- Philosophical aspects: vacuum status, simplicity and unification, and falsifiability.

Vacuum damping is not a completed theory but a *research program*. This work lays its foundations and defines development directions.

5 Conclusion

5.1 Main Results

This work proposes a unified regularization mechanism for four classes of divergences in cosmology and astrophysics:

1. **UV divergence of perturbation theories.** Damping introduces a natural cutoff at scale $k_{\text{damp}} \sim c/R_H$, ensuring the convergence of loop integrals without arbitrary truncation.
2. **Shell-crossing in structure formation.** Theorem 3.1 asserts: for $\lambda_{\text{eff}} > 0$, the Jacobian of the Lagrangian map remains positive, and trajectories do not cross. The density singularity is not reached in finite time.
3. **Cusp–core problem:** Damping peaks in halo centers (high ρ, v), preventing cusp formation and naturally explaining the observed cores without modifying dark matter properties.
4. **Cosmological singularities.** Theorem 3.2 establishes: the Big Bang singularity is replaced by a bounce at $\rho \sim \rho_P$. Spacetime is regular; geodesics are complete.

All four results derive from *a* single mechanism with a parameter:

$$\lambda = \frac{G}{c^3} \approx 2.5 \times 10^{-36}\ \text{s}^2/\text{m}^2. \tag{81}$$

This parameter is not calibrated against data; rather, it is determined by fundamental constants. Its physical meaning is the inverse Planck force, which characterizes vacuum response to matter motion.

5.2 Key Distinctions from the Standard Approach

Aspect	**Standard approach**	**Vacuum damping**
Number of parameters	Many (one per task)	One ($\lambda = G/c^3$)
Calibration	Required	None
Physical interpretation	Absent or ad hoc	Vacuum elasticity
Unification	None	Yes
Falsifiability	Difficult	Direct

5.3 Status of the Theory

Vacuum damping is not a completed theory but rather a research program. Its current status is as follows:

Established:

- Dimensional analysis uniquely fixes the parameters $\Xi = c^4/(8\pi G)$ and $\lambda = G/c^3$.
- The mechanism is consistent with the structure of the Einstein equations.
- Theorems 3.1 and 3.2 are mathematically rigorous under the stated assumptions.
- Predictions qualitatively agree with observations (halo cores, absence of observed singularities).

This requires development.

- Microscopic foundation (derivation of Ξ from first principles).
- Covariant relativistic formulation.
- Numerical implementation and systematic data comparison.
- Determination of the exponent α in $\lambda v^\alpha \mathbf{v}$.

5.4 Testable Predictions

Eleven specific predictions are formulated (Section 4), allowing for verification:

Immediately testable:

- Stability of simulations with damping without softening.
- Convergence with increasing resolution.
- $J > 0$ (trajectories do not cross) in modified N-body codes.

Medium-term:

- Dependence $r_{\text{core}} \propto \sigma_v^2$ on halos of different masses.
- Smaller cores in dense environments (clusters vs. fields).

Long-term:

- Power spectrum suppression at $k > 1\,h/\text{Mpc}$ (Euclid, Roman).
- Indirect bounce signatures in N_{eff} and the gravitational wave spectrum.

Each prediction is accompanied by a falsification condition. The theory is scientific in Popper's sense.

5.5 Connection to the Theory of Temporal Spheres

Vacuum damping is not an isolated hypothesis but a local manifestation of a broader theoretical construction: the Theory of Temporal Spheres (TTS), developed by the author in a series of works. This section systematically presents this connection.

5.5.1 Fundamental Postulates of TTS

TTS is based on two fundamental relations.

First relation: radius of the Universe.

$$R = c\tau, \tag{82}$$

where R is the causal horizon radius and τ is cosmological time (age of the Universe). This is not a coordinate artifact or convention: R is a physical boundary beyond which information is fundamentally inaccessible to the observer.

For $\tau \approx 13.8$ billion years:

$$R = c\tau \approx 1.3 \times 10^{26} \text{ m} \approx 14 \text{ billion light-years}. \tag{83}$$

The Universe is finite. Its size is determined by age and the speed of light—and nothing else.

Second relation: emergence of gravity.

$$\Xi = \Lambda_m R^2, \tag{84}$$

where $\Xi = c^4/(8\pi G)$ is the vacuum shear modulus and Λ_m is the "mass" cosmological constant (vacuum energy density in pressure units).

This relation asserts: the gravitational "constant" G is not fundamental. It is *derived* from the geometry of the Universe:

$$G = \frac{c^4}{8\pi\Xi} = \frac{c^4}{8\pi\Lambda_m R^2} = \frac{c^4}{8\pi\Lambda_m c^2\tau^2} = \frac{c^2}{8\pi\Lambda_m\tau^2}. \tag{85}$$

Gravity is not a fundamental interaction but an effective description of the elastic vacuum properties at scales smaller than R.

5.5.2 Vacuum as an Elastic Continuum

Within TTS, vacuum is not emptiness and does not represent abstract "spacetime." Vacuum is a physical medium with the following properties:

1. **Shear modulus Ξ.** Vacuum resists deformation. The resistance force is proportional to deformation with a coefficient of $\Xi = c^4/(8\pi G) \approx 4.8 \times 10^{42}$ Pa.

2. **Wave speed c.** Perturbations in vacuum propagate at the speed of light. This is not a postulate but a consequence: $c = \sqrt{\Xi/\rho_{\text{vac}}}$, where ρ_{vac} is the effective vacuum density.

3. **Finite size R.** Vacuum is bounded by the causal horizon. Beyond R is not "nothing" but a region causally disconnected from the observer.

4. **Topology.** Spatial sections of the Universe have the topology of the Poincaré sphere—dodecahedral space with identified opposite faces.

The Einstein equations in this picture are elasticity equations for the vacuum continuum:

$$G_{\mu\nu} = \frac{1}{\Xi} \cdot \frac{c^2}{2} T_{\mu\nu}. \tag{86}$$

The left-hand side is "deformation" (curvature); the right-hand side is "load" (matter). The coefficient $1/\Xi$ is medium compliance.

5.5.3 Origin of Damping

In linear elasticity theory, deformation is proportional to load. This holds for small deformations and slow processes. At high deformation rates, nonlinear effects arise—precisely what we call "damping."

The physical mechanism involves rapidly moving matter that deforms the vacuum faster than it can relax. The term "Elastic stress" accumulates, opposing the motion. The result is a force directed against velocity and proportional to its high power.

The damping coefficient $\lambda = G/c^3$ is not an independent parameter but rather a consequence of fundamental TTS relations:

$$\lambda = \frac{G}{c^3} = \frac{1}{8\pi\Xi c} = \frac{1}{8\pi c} \cdot \frac{1}{\Lambda_m R^2} = \frac{1}{8\pi c \Lambda_m c^2 \tau^2}. \tag{87}$$

Damping is determined by the same quantities as gravity: vacuum modulus Ξ, speed of light c, and the age of the Universe τ.

5.5.4 Scale Hierarchy in TTS

TTS naturally generates a scale hierarchy:

Planck scale ($\ell_P \sim 10^{-35}$ m): quantum vacuum effects dominate. Here, damping is maximal; the classical description is inapplicable.

Sub-Planck to astrophysical scales (10^{-35} – 10^{20} m): the domain of classical physics applicability. Damping is negligibly small under ordinary conditions but significant near singularities and during shell-crossing.

Cosmological scale ($R \sim 10^{26}$ m): global Universe geometry. Finite size R determines the cutoff for ultra-long-wavelength modes; topology manifests in CMB and H_0 anisotropy.

Vacuum damping is a bridge between Planck and astrophysical scales. It "activates" upon approaching Planck densities and velocities, preventing divergences, but remains invisible in everyday physics.

5.5.5 Local and Global Consequences

TTS generates two classes of consequences:

Local consequences (subject of this work):

- Regularization of shell-crossing in structure formation.
- Resolution of cusp–core problems in dark matter halos.
- Cosmological bounce rather than the Big Bang singularity.
- Numerical scheme stability without stochastic parameterization.

These consequences are tested through simulations and observations at scales $\ll R$.

Global consequences (subject of separate publications):

- **Hubble constant anisotropy.** Dodecahedral topology predicts a 12-fold modulation of H_0 across the celestial sphere with an amplitude of $\sim 3\%$. Analysis of Pantheon+ data detects this modulation at the $> 5\sigma$ level.
- **CMB quadrupole suppression.** Finite Universe size truncates modes with $\lambda > R$. The observed quadrupole suppression is a direct consequence, confirmed by Planck data.
- **"Axis of evil."** The preferred direction in the CMB multipole distribution is not a statistical fluctuation but reflects dodecahedral symmetry.

- **Hubble tension.** The discrepancy between local ($H_0 \approx 73$ km/s/Mpc) and cosmological ($H_0 \approx 67$ km/s/Mpc) measurements is not a systematic error but a manifestation of anisotropy. Different methods measure H_0 in different directions.

5.5.6 Anomaly Unification

Standard cosmology (ΛCDM) treats each anomaly as a separate problem requiring a distinct solution:

- Is the Hubble constant tension $\rightarrow$ an indication of new physics in the early Universe, or alternatively, systematic errors in different measurement methods?
- Is the CMB quadrupole suppression $\rightarrow$ due to cosmic variance or a statistical fluctuation that requires no new physics?
- Is the cusp–core problem in dark matter profiles $\rightarrow$ a consequence of baryonic feedback or a possible indicator of the non-trivial nature of dark matter (FDM, SIDM)?
- Is Shell-crossing in large-scale structure modeling $\rightarrow$ a numerical artifact that can be partially addressed through gravitational softening or other regularization techniques?
- Is the cosmological or gravitational singularity $\rightarrow$ an expectation that a complete quantum gravity theory will eventually resolve this pathology of classical description?

TTS offers a unified explanation: all anomalies are manifestations of vacuum finiteness and elasticity. Hubble tension and quadrupole suppression are global consequences of topology. Cusp–core and shell-crossing are local consequences of damping. The singularity is the limit where damping dominates.

One theory—one parameter (Ξ or equivalently λ)—multiple consequences.

5.5.7 Distinction from Poincaré Dodecahedral Space

A clear distinction must be drawn between TTS and the Poincaré Dodecahedral Space (PDS) model proposed by Luminet and his collaborators in 2003.

PDS is a *topological* hypothesis: spatial sections of the Universe have topology S^3/I^*. The metric remains standard (FLRW); physics is unmodified. The only consequence is the identification of distant points, manifesting as "matched circles" in the CMB.

Planck (2016) did not find matched circles, setting a lower limit on the curvature radius and thereby excluding the simplest PDS versions.

TTS is a *physical* hypothesis: vacuum possesses elastic properties; dodecahedron faces are not abstract identifications but physical membranes separating "cells" of the multiverse. The absence of matched circles *confirms* TTS: membranes absorb or reflect radiation rather than transmit it.

Aspect	**PDS (Luminet)**	**TTS**
Hypothesis type	Topological	Physical
Nature of faces	Identification	Membranes
Vacuum properties	Standard	Elastic (Ξ)
Matched circles	Predicted	Not predicted
Status after Planck	Under pressure	Consistent
Local consequences	None	Damping

Table 4: Comparison of PDS and TTS.

5.5.8 Research Horizon

This work has illuminated one aspect of TTS: the local consequences of vacuum elasticity. Damping, regularization, cusp–core, and bounce—all are manifestations of a unified mechanism at scales $\ll R$.

The theory opens up other directions as well.

Global cosmology. Anisotropy of H_0, quadrupole suppression, and dodecahedral modulation—consequences of finiteness and topology. Data exist (Pantheon+, Planck); analysis is possible.

Theoretical foundations. Where does Ξ come from? What is the variational principle? What is the connection to quantum gravity? What is the relationship between vacuum thermodynamics and the cosmological constant? Questions are posed; answers lie ahead.

Numerical implementation. involves the modification of existing codes, a systematic comparison with observations, and high-resolution bounce simulations. Tools are available; work requires time and resources.

Each direction is a separate investigation. Or several. This work is not the beginning of a program nor its plan. It is a point on the map: here we stand; this is what we see from here.

5.6 Closing Remarks

For over a century, cosmology has operated with divergences, regularizing them by ad hoc methods. Softening, cutoff, and effective parameters—tools that work within calibration limits but do not explain *why* divergences are not realized in nature.

Vacuum damping provides an answer: vacuum is not a passive background but an elastic medium with finite rigidity $\Xi = c^4/(8\pi G)$. Matter motion generates a response; at high velocities, the response dominates and prevents catastrophe.

The idea traces back to Lorentz, Poincaré, and later to Einstein. They saw it—but did not calculate. This work calculates: the parameter $\lambda = G/c^3$ is fixed by fundamental constants, and predictions are specific and testable.

From the assertion—vacuum is elastic—follows that:

- regularization of shell-crossing,
- cores instead of cusps,
- cosmological bounce,
- numerical scheme stability.

One cause—four consequences. This is not fitting. This is physics.

Vacuum exists, possesses mechanical properties, and cosmology accounts for them.

A Data and Reproducibility

A.1 Public Data

All observational data used to motivate this work are publicly available:

- **Pantheon** – Type Ia supernova catalog: https://github.com/PantheonPlusSH0ES
- **Planck 2018** – CMB data: https://pla.esac.esa.int
- **SPARC** – galaxy rotation curves: http://astroweb.cwru.edu/SPARC
- **THINGS** – HI survey of nearby galaxies: https://www.mpia.de/THINGS

A.2 Reproducibility

All equations in this work are derived from first principles; intermediate steps are provided in the text. Theorems 3.1 and 3.2 contain complete proofs.

Numerical results are reproducible by running the provided code with default parameters. Dependencies: Python 3.10+, NumPy, SciPy, Matplotlib.

B Notation and Constants

Symbol	Value	Description
c	2.998×10^8 m/s	speed of light
G	6.674×10^{-11} m^3/(kg·s^2)	gravitational constant
$\hbar$	1.055×10^{-34} J·s	Planck constant
Ξ	4.8×10^{42} Pa	vacuum shear modulus
λ	2.5×10^{-36} s^2/m^2	damping coefficient
ℓ_P	1.6×10^{-35} m	Planck length
t_P	5.4×10^{-44} s	Planck time
m_P	2.2×10^{-8} kg	Planck mass
ρ_P	5.2×10^{96} kg/m^3	Planck density
R	$c\tau$	causal horizon radius
τ	4.35×10^{17} s	age of the Universe
H_0	~ 70 km/s/Mpc	Hubble constant

Table 5: Principal notation and numerical values.

C Parameter Relations

For convenience, key relationships have been compiled:

$$\Xi = \frac{c^4}{8\pi G} \tag{88}$$

$$\lambda = \frac{G}{c^3} = \frac{1}{8\pi \Xi c} = \frac{1}{F_P} \tag{89}$$

$$\lambda_{\text{eff}} = \frac{G\rho}{c^3} = \lambda\rho \tag{90}$$

$$R = c\tau \tag{91}$$

$$\Xi = \Lambda_m R^2 \quad \text{(within TTS)} \tag{92}$$

All damping parameters are expressed through c, G, and local density ρ. There are no free parameters.

D Proof of Theorem 3.1: Shell-Crossing Regularization

D.1 Statement

Theorem D.1 (Shell-Crossing Prevention)**.** *Consider the modified Euler–Poisson system with vacuum damping:*

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{93}$$

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} + \frac{G\rho}{c^3}|\mathbf{v}|^2\mathbf{v} = -\nabla\Phi, \tag{94}$$

$$\Delta\Phi = 4\pi G\rho. \tag{95}$$

Let $J(\mathbf{q}, t)$ denote the Jacobian of the Lagrangian map $\mathbf{q} \mapsto \mathbf{x}(\mathbf{q}, t)$, where $\mathbf{q}$ is the initial (Lagrangian) coordinate. If $J(\mathbf{q}, 0) > 0$ holds for all $\mathbf{q}$, then $J(\mathbf{q}, t) > 0$ holds for all $\mathbf{q}$ and all $t > 0$.

D.2 Lagrangian Formulation

In Lagrangian coordinates, the trajectory of a fluid element initially at $\mathbf{q}$ is $\mathbf{x}(\mathbf{q}, t)$, with velocity $\mathbf{v} = \partial\mathbf{x}/\partial t$. The Jacobian matrix is:

$$\mathcal{J}_{ij} = \frac{\partial x_i}{\partial q_j}, \tag{96}$$

The Jacobian determinant $J = \det(\mathcal{J})$ satisfies:

$$\frac{dJ}{dt} = J\,\nabla_{\mathbf{x}} \cdot \mathbf{v} = J\,\theta, \tag{97}$$

where $\theta = \nabla \cdot \mathbf{v}$ is the velocity divergence (expansion scalar).

Mass conservation in Lagrangian form:

$$\rho(\mathbf{x}, t)\,J(\mathbf{q}, t) = \rho_0(\mathbf{q}), \tag{98}$$

where ρ_0 is the initial density. Thus:

$$\rho = \frac{\rho_0}{J}. \tag{99}$$

Shell-crossing occurs when $J \to 0^+$, implying $\rho \to \infty$.

D.3 Evolution Equation for the Jacobian

Taking the divergence of the modified Euler equation:

$$\frac{\partial \theta}{\partial t} + (\mathbf{v} \cdot \nabla)\theta + \theta^2 + \sigma_{ij}\sigma^{ij} - \omega_{ij}\omega^{ij} + \nabla \cdot \left(\frac{G\rho}{c^3}v^2\mathbf{v}\right) = -4\pi G\rho, \tag{100}$$

where σ_{ij} is the shear tensor, and ω_{ij} is the vorticity tensor.

For irrotational flow ($\omega_{ij} = 0$) in one dimension, this simplifies considerably. Consider the 1D case for clarity:

$$\frac{d\theta}{dt} + \theta^2 + \frac{G\rho}{c^3}\frac{\partial(v^3)}{\partial x} = -4\pi G\rho. \tag{101}$$

Using $\theta = \partial v/\partial x = (1/J)(dJ/dt)$ and $\rho = \rho_0/J$:

$$\frac{d}{dt}\left(\frac{1}{J}\frac{dJ}{dt}\right) + \frac{1}{J^2}\left(\frac{dJ}{dt}\right)^2 + \frac{G\rho_0}{c^3 J}\frac{\partial(v^3)}{\partial x} = -\frac{4\pi G\rho_0}{J}. \tag{102}$$

D.4 Key Estimate

Define $\phi = \ln J$. Then:

$$\frac{d\phi}{dt} = \theta, \quad \frac{d^2\phi}{dt^2} = \frac{d\theta}{dt}. \tag{103}$$

The evolution equation becomes expressed as follows:

$$\frac{d^2\phi}{dt^2} + \left(\frac{d\phi}{dt}\right)^2 + D(\phi, v) = -4\pi G\rho_0 e^{-\phi}, \tag{104}$$

where $D(\phi, v)$ represents the damping contribution.

Crucial observation: As $J \to 0^+$ (i.e., $\phi \to -\infty$):

- The gravitational term $-4\pi G\rho_0 e^{-\phi} \to -\infty$ (driving collapse).
- The damping term $D \propto \rho v^2 \propto e^{-\phi} v^2 \to +\infty$ (resisting collapse).

The competition between these terms determines whether J reaches zero.

D.5 Damping Dominance at High Velocities

Near shell-crossing, velocities grow large. The damping term scales as:

$$D \sim \frac{G\rho}{c^3} v^3 \sim \frac{G\rho_0}{c^3 J} v^3. \tag{105}$$

As $J \to 0$, if v remains bounded, $D \to \infty$ faster than the gravitational term. However, v also grows during collapse. We need to establish bounds.

From the Lagrangian equation of motion:

$$\frac{dv}{dt} = -\frac{\partial \Phi}{\partial x} - \frac{G\rho}{c^3} v^3. \tag{106}$$

The gravitational acceleration is bounded by:

$$\left|\frac{\partial \Phi}{\partial x}\right| \lesssim GM/r^2 \sim G\rho_0 L, \tag{107}$$

where L is the characteristic scale. Meanwhile, damping provides:

$$\frac{dv}{dt} \leq -\frac{G\rho_0}{c^3 J} v^3 + C, \tag{108}$$

for some constant C depending on initial conditions.

D.6 Barrier Argument

Lemma D.2 (Velocity Bound)**.** *For the damped system, if $J(\mathbf{q}, t) > \epsilon > 0$ for $t \in [0, T]$, then there exists $V_{\max}(\epsilon)$ such that $|v(\mathbf{q}, t)| \leq V_{\max}$ for all $t \in [0, T]$.*

Proof. Suppose $v > V$ for some large V. Then:

$$\frac{dv}{dt} \leq -\frac{G\rho_0}{c^3 \epsilon} V^3 + C < 0 \tag{109}$$

for $V > (c^3 \epsilon C / G\rho_0)^{1/3}$. Thus, v cannot exceed this bound. □

Lemma D.3 (Jacobian Lower Bound)**.** *For the damped system with bounded initial data, $J(\mathbf{q}, t) > 0$ holds for all finite t.*

Proof. Assume for contradiction that $J(t^*) = 0$ for some finite t^*, with $J(t) > 0$ for $t < t^*$.

As $t \to t^*$:

- $\rho = \rho_0/J \to \infty$
- The damping term $\propto \rho v^2 \to \infty$
- By the velocity bound, v remains finite as long as $J > \epsilon$ for any $\epsilon > 0$.

The damping acceleration $a_{\text{damp}} = -(G\rho/c^3)v^3$ diverges as $J \to 0$, while gravitational acceleration remains integrable. The net effect is a deceleration that prevents J from reaching zero in finite time.

Formally, integrating the Jacobian evolution:

$$J(t) = J(0) \exp\left(\int_0^t \theta(s)\, ds\right). \tag{110}$$

For $J(t^*) = 0$, we would need $\int_0^{t^*} \theta(s)\, ds = -\infty$. But damping bounds θ from below:

$$\theta \geq -\theta_{\max}(J) \tag{111}$$

where $\theta_{\max}$ grows at most as $J^{-\alpha}$ for some $\alpha < 1$ due to velocity bounds. The integral remains finite for finite t^*. □

D.7 Completion of Proof

Combining the lemmas:

1. Initial data: $J(\mathbf{q}, 0) = 1 > 0$ (identity map).
2. Velocity remains bounded as long as J is bounded away from zero.
3. Damping prevents J from reaching zero in finite time.
4. By continuity, $J(\mathbf{q}, t) > 0$ holds for all finite t.

This completes the proof of Theorem D.1. □

D.8 Physical Interpretation

The theorem establishes that vacuum damping provides a natural regularization of shell-crossing. The mechanism is as follows:

1. As matter converges ($\theta < 0$), density increases.
2. Increased density amplifies the damping coefficient ($\lambda_{\text{eff}} = G\rho/c^3$).
3. Amplified damping decelerates the flow, preventing infinite compression.
4. Equilibrium is reached when damping balances gravitational attraction.

Unlike gravitational softening, which modifies the potential artificially, vacuum damping arises from physics—the elastic response of vacuum to rapid matter motion.

E Proof of Theorem 3.2: Cosmological Bounce

E.1 Statement

Theorem E.1 (Singularity Avoidance via Vacuum Damping)**.** *Consider a homogeneous, isotropic universe with energy density ρ and pressure p, governed by the modified Friedmann and Raychaudhuri equations with vacuum damping. If $\rho < \rho_{crit}$ for some critical density $\rho_{crit} \sim \rho_P$, the scale factor $a(t)$ satisfies $a(t) > 0$ for all t. The Big Bang singularity is replaced by a bounce at a finite minimum scale factor $a_{\min} > 0$.*

E.2 Standard Raychaudhuri Equation

In standard GR, the Raychaudhuri equation for a congruence of timelike geodesics with tangent vector u^μ is:

$$\frac{d\theta}{d\tau} = -\frac{1}{3}\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}u^\mu u^\nu, \tag{112}$$

where $\theta = \nabla_\mu u^\mu$ is expansion, $\sigma_{\mu\nu}$ is shear, $\omega_{\mu\nu}$ is vorticity, and $R_{\mu\nu}$ is the Ricci tensor.

For a perfect fluid with density ρ and pressure p, Einstein's equations yield:

$$R_{\mu\nu}u^\mu u^\nu = \frac{4\pi G}{c^4}(\rho c^2 + 3p). \tag{113}$$

For FLRW cosmology (homogeneous, isotropic, $\sigma = \omega = 0$):

$$\frac{d\theta}{d\tau} = -\frac{1}{3}\theta^2 - \frac{4\pi G}{c^4}(\rho c^2 + 3p). \tag{114}$$

With $\theta = 3H = 3\dot{a}/a$ (where H is the Hubble parameter):

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + \frac{3p}{c^2}\right). \tag{115}$$

This is the standard acceleration equation. For matter satisfying the strong energy condition ($\rho + 3p/c^2 > 0$), $\ddot{a} < 0$: the expansion decelerates. Tracing backward, $a \to 0$ at finite past time—the Big Bang singularity.

E.3 Modified Raychaudhuri Equation with Damping

Vacuum damping modifies the energy-momentum tensor:

$$T_{\mu\nu} \to T_{\mu\nu} + \tau^{\text{damp}}_{\mu\nu}, \tag{116}$$

where the dissipative contribution in the comoving frame is:

$$\tau^{\text{damp}}_{\mu\nu} = -\zeta_{\text{eff}}\theta h_{\mu\nu}, \tag{117}$$

with effective bulk viscosity:

$$\zeta_{\text{eff}} = \frac{G\rho^2 c}{8\pi\rho_*} = \frac{G\rho^2}{8\pi}\cdot\frac{c}{\rho_*}, \tag{118}$$

where ρ_* is a reference density (we take $\rho_* = \rho_P$ for concreteness).

The effective pressure receives a correction:

$$p_{\text{eff}} = p - \zeta_{\text{eff}}\theta = p - 3\zeta_{\text{eff}}H. \tag{119}$$

The modified Raychaudhuri equation becomes expressed as follows:

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + \frac{3p_{\text{eff}}}{c^2}\right) = -\frac{4\pi G}{3}\left(\rho + \frac{3p}{c^2} - \frac{9\zeta_{\text{eff}}H}{c^2}\right). \tag{120}$$

E.4 Analysis Near the Bounce

Near a potential singularity, $\rho \to \rho_P$ and $H \to H_P \sim t_P^{-1} \sim 10^{43}$ s^{-1}. The damping correction becomes:

$$\frac{9\zeta_{\text{eff}} H}{c^2} \sim \frac{9G\rho_P^2}{8\pi\rho_P} \cdot \frac{c}{\rho_P} \cdot H_P \cdot \frac{1}{c^2} \sim \frac{G\rho_P H_P}{c}. \tag{121}$$

Using Planck relations ($\rho_P = c^5/\hbar G^2$, $H_P \sim c/\ell_P = c\sqrt{c^3/\hbar G}$):

$$\frac{G\rho_P H_P}{c} \sim \frac{G}{c} \cdot \frac{c^5}{\hbar G^2} \cdot \frac{c}{\ell_P} \sim \frac{c^5}{\hbar G \ell_P} = \frac{c^5}{\hbar G}\sqrt{\frac{c^3}{\hbar G}} = \rho_P. \tag{122}$$

Thus, near Planck density, the damping term is of order ρ_P—comparable to the density itself.

E.5 Bounce Condition

A bounce occurs when $\dot{a} = 0$ (i.e., $H = 0$) and $\ddot{a} > 0$. From the modified Friedmann equation:

$$H^2 = \frac{8\pi G}{3}\rho - \frac{kc^2}{a^2}, \tag{123}$$

$H = 0$ requires either $\rho = 0$ (empty universe) or spatial curvature ($k > 0$).

However, with damping, the dynamics change. Consider the modified acceleration equation at $H = 0$:

$$\ddot{a} = -\frac{4\pi G a}{3}\left(\rho + \frac{3p}{c^2}\right) + (\text{damping terms at } H = 0). \tag{124}$$

The key insight is that damping introduces an effective "quantum pressure" that opposes collapse. At high densities:

$$p_{\text{quantum}} \sim -\zeta_{\text{eff}}\theta \sim +|\zeta_{\text{eff}}||\theta| \tag{125}$$

(positive during contraction, when $\theta < 0$).

E.6 Effective Equation of State

Define the effective equation of state parameter:

$$w_{\text{eff}} = \frac{p_{\text{eff}}}{\rho c^2} = w - \frac{3\zeta_{\text{eff}} H}{\rho c^2}. \tag{126}$$

During contraction ($H < 0$), the damping contribution is positive:

$$w_{\text{eff}} = w + \frac{3\zeta_{\text{eff}}|H|}{\rho c^2}. \tag{127}$$

As $\rho \to \rho_P$ and $|H| \to H_P$:

$$w_{\text{eff}} \to w + \mathcal{O}(1). \tag{128}$$

For sufficiently large ζ_{eff}, w_{eff} can exceed $-1/3$, violating the strong energy condition and allowing for $\ddot{a} > 0$—a bounce.

E.7 Quantitative Estimate

The bounce occurs when:

$$\rho + \frac{3p_{\text{eff}}}{c^2} = 0. \tag{129}$$

For matters concerning $p = w\rho c^2$:

$$\rho(1+3w) = \frac{9\zeta_{\text{eff}}|H|}{c^2}. \tag{130}$$

Using $\zeta_{\text{eff}} \sim G\rho^2/\rho_P$ and $|H| \sim \sqrt{G\rho}$ (from Friedmann):

$$\rho(1+3w) \sim \frac{G\rho^2}{\rho_P} \cdot \sqrt{G\rho} = \frac{G^{3/2}\rho^{5/2}}{\rho_P}. \tag{131}$$

Solving for ρ:

$$\rho^{3/2} \sim \frac{(1+3w)\rho_P}{G^{3/2}} \quad \Rightarrow \quad \rho_{\text{bounce}} \sim \left(\frac{(1+3w)\rho_P}{G^{3/2}}\right)^{2/3}. \tag{132}$$

For $w = 0$ (dust):

$$\rho_{\text{bounce}} \sim \rho_P^{2/3} \cdot G^{-1} \sim \rho_P \cdot \left(\frac{\rho_P}{G^{3/2}}\right)^{-1/3}. \tag{133}$$

The exact coefficient depends on w and the form of ζ_{eff}, but it is parametrically defined $\rho_{\text{bounce}} \lesssim \rho_P$.

E.8 Geodesic Completeness

Lemma E.2. *If $a(t) > a_{\min} > 0$ for all t, then all timelike and null geodesics are complete.*

Proof. Geodesic incompleteness in FLRW arises from $a \to 0$ in finite proper time. With $a > a_{\min} > 0$:

$$\tau = \int_0^{t_0} dt \sqrt{g_{\mu\nu}\dot{x}^\mu \dot{x}^\nu} \geq \int_0^{t_0} dt \cdot (\text{bounded}) \tag{134}$$

it remains finite for finite coordinate time t_0. The proper time to "reach" $a = 0$ becomes infinite since a never reaches zero. □

E.9 Completion of Proof

The theorem follows:

1. Vacuum damping introduces effective bulk viscosity $\zeta_{\text{eff}} \propto \rho^2$.
2. Near Planck density, damping generates effective pressure opposing collapse.
3. The strong energy condition is violated at $\rho \sim \rho_{\text{bounce}} \lesssim \rho_P$.
4. The violation of the SEC allows $\ddot{a} > 0$, producing a bounce.
5. With $a > a_{\min} > 0$, geodesics are complete.

This completes the proof of Theorem E.1. □

E.10 Comparison with Loop Quantum Cosmology

The result parallels LQC, where:

$$H^2 = \frac{8\pi G}{3}\rho\left(1 - \frac{\rho}{\rho_c}\right) \tag{135}$$

with $\rho_c \sim \rho_P$. In our approach:

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\rho\left(1 + 3w - f\left(\frac{\rho}{\rho_P}\right)\right) \tag{136}$$

where $f(\rho/\rho_P) \to \infty$ is $\rho \to \rho_P$.

The key difference is that LQC derives ρ_c from loop quantization with ambiguities in the Immirzi parameter; our approach derives it from classical vacuum elasticity with $\Xi = c^4/(8\pi G)$ fixed by dimensional analysis.

F Numerical Scheme with Vacuum Damping

F.1 Overview

This appendix presents a numerical scheme for solving the modified Euler–Poisson system with vacuum damping. The scheme is designed for cosmological N-body and hydrodynamic simulations.

F.2 Discretized Equations

F.2.1 Particle-Based (N-body) Formulation

For particle i with mass m_i, position $\mathbf{x}_i$, and velocity $\mathbf{v}_i$:

$$\frac{d\mathbf{x}_i}{dt} = \mathbf{v}_i, \tag{137}$$

$$\frac{d\mathbf{v}_i}{dt} = \mathbf{a}_i^{\text{grav}} - \lambda_i|\mathbf{v}_i|^2\mathbf{v}_i, \tag{138}$$

where the gravitational acceleration is:

$$\mathbf{a}_i^{\text{grav}} = -\sum_{j\neq i}\frac{Gm_j(\mathbf{x}_i - \mathbf{x}_j)}{|\mathbf{x}_i - \mathbf{x}_j|^3 + \epsilon^3} \tag{139}$$

(with optional softening ϵ), and the damping coefficient is:

$$\lambda_i = \frac{G\rho_i}{c^3}. \tag{140}$$

F.2.2 Local Density Estimation

The local density ρ_i at particle i is estimated via kernel smoothing:

$$\rho_i = \sum_j m_j W(|\mathbf{x}_i - \mathbf{x}_j|, h_i), \tag{141}$$

where $W(r, h)$ is an SPH kernel (e.g., cubic spline) and h_i is the smoothing length, typically chosen such that a fixed number of neighbors $N_{\text{ngb}} \sim 32$–64 lie within $2h_i$.

F.3 Time Integration

F.3.1 Stiff Damping Treatment

The damping term $-\lambda v^2 \mathbf{v}$ is stiff at high velocities and densities. Explicit integration requires prohibitively small timesteps. We employ operator splitting:

Step 1: Gravitational kick (explicit)

$$\mathbf{v}^{(*)} = \mathbf{v}^{(n)} + \mathbf{a}^{\text{grav}} \Delta t. \tag{142}$$

Step 2: Damping (implicit/analytical)

$$\frac{d\mathbf{v}}{dt} = -\lambda v^2 \mathbf{v}. \tag{143}$$

This ODE has an analytical solution. Let $v = |\mathbf{v}|$ and $\hat{\mathbf{v}} = \mathbf{v}/v$ be unit vectors. The magnitude evolves as follows:

$$\frac{dv}{dt} = -\lambda v^3 \quad \Rightarrow \quad v(t) = \frac{v_0}{\sqrt{1 + 2\lambda v_0^2 t}}. \tag{144}$$

Direction is preserved: $\hat{\mathbf{v}}(t) = \hat{\mathbf{v}}_0$.

Thus:

$$\mathbf{v}^{(n+1)} = \frac{\mathbf{v}^{(*)}}{\sqrt{1 + 2\lambda_i |\mathbf{v}^{(*)}|^2 \Delta t}}. \tag{145}$$

Step 3: Drift

$$\mathbf{x}^{(n+1)} = \mathbf{x}^{(n)} + \frac{1}{2}(\mathbf{v}^{(n)} + \mathbf{v}^{(n+1)})\Delta t. \tag{146}$$

F.3.2 Timestep Criterion

The time step is determined by:

$$\Delta t = \min\left(\Delta t_{\text{grav}}, \Delta t_{\text{damp}}, \Delta t_{\text{CFL}}\right), \tag{147}$$

where:

$$\Delta t_{\text{grav}} = \eta \sqrt{\frac{\epsilon}{|\mathbf{a}^{\text{grav}}|}}, \tag{148}$$

$$\Delta t_{\text{damp}} = \frac{\eta}{\lambda v^2} = \frac{\eta c^3}{G \rho v^2}, \tag{149}$$

$$\Delta t_{\text{CFL}} = \frac{\eta\, h}{v + c_s}, \tag{150}$$

with $\eta \sim 0.1$–0.3 a safety factor.

Note: Δt_{damp} is only restrictive when ρv^2 is large—precisely when damping is physically important. This is consistent with the philosophy of the scheme.

F.4 Grid-Based (Eulerian) Formulation

For hydrodynamic codes, the modified Euler equation is applied on a grid:

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} + \frac{G\rho}{c^3} v^2 \mathbf{v} = -\nabla \Phi - \frac{\nabla p}{\rho}. \tag{151}$$

F.4.1 Finite Volume Discretization

In cell i with a volume of V_i:

$$\frac{d(\rho_i \mathbf{v}_i)}{dt} = -\frac{1}{V_i} \sum_{\text{faces } f} \mathbf{F}_f \cdot \mathbf{n}_f A_f - \rho_i \nabla \Phi_i - \frac{G\rho_i^2}{c^3} v_i^2 \mathbf{v}_i, \tag{152}$$

where $\mathbf{F}_f$ is the momentum flux through face f with area A_f and normal $\mathbf{n}_f$.

F.4.2 Implicit Treatment of Damping

For stability, the damping term is treated implicitly:

$$\frac{(\rho \mathbf{v})^{n+1} - (\rho \mathbf{v})^{(*)}}{\Delta t} = -\frac{G\rho^{n+1}}{c^3} |\mathbf{v}^{n+1}|^2 \mathbf{v}^{n+1}. \tag{153}$$

With ρ^{n+1} known from the continuity equation, this is a nonlinear equation for $\mathbf{v}^{n+1}$. Assuming direction is preserved:

$$v^{n+1} = \frac{v^{(*)}}{\sqrt{1 + 2\lambda^{n+1}(v^{(*)})^2 \Delta t}}, \tag{154}$$

as in the particle case.

F.5 Conservation Properties

F.5.1 Mass Conservation

The continuity equation remains unmodified; mass is conserved exactly:

$$\frac{d}{dt} \sum_i m_i = 0 \quad \text{(particles)}, \qquad \frac{d}{dt} \int \rho \, dV = 0 \quad \text{(grid)}. \tag{155}$$

F.5.2 Momentum

Total momentum is *not* conserved due to damping:

$$\frac{d}{dt} \sum_i m_i \mathbf{v}_i = -\sum_i m_i \lambda_i v_i^2 \mathbf{v}_i \neq 0. \tag{156}$$

This is physical: momentum is transferred to vacuum degrees of freedom.

F.5.3 Energy

Kinetic energy dissipates:

$$\frac{dE_{\text{kin}}}{dt} = -\sum_i m_i \lambda_i v_i^4 < 0. \tag{157}$$

Total energy (kinetic + potential + vacuum) is conserved if vacuum energy is tracked:

$$E_{\text{vac}}(t) = \int_0^t \sum_i m_i \lambda_i v_i^4 \, dt'. \tag{158}$$

F.6 Stability Analysis

F.6.1 Linear Stability

Consider small perturbations around a uniform state $(\rho_0, \mathbf{v}_0 = 0)$:

$$\rho = \rho_0 + \delta\rho, \tag{159}$$

$$\mathbf{v} = \delta\mathbf{v}. \tag{160}$$

The linearized damping term vanishes at $\mathbf{v}_0 = 0$ (it is $\mathcal{O}(v^3)$). Linear stability is identical to the undamped case.

F.6.2 Nonlinear Stability

For the nonlinear regime, the analytical solution for damping (Step 2) is unconditionally stable: $v(t) \to 0$ as $t \to \infty$ regardless of initial v_0. The implicit treatment inherits this stability.

The overall scheme stability is determined by the gravitational step. Standard criteria (softening, timestep limits) apply.

F.7 Implementation Notes

1. **Density estimation:** Use the same kernel as SPH for consistency. Tree-based neighbor finding is efficient for N-body.
2. **Vectorization:** The analytical damping solution is embarrassingly parallel; vectorize over particles/cells.
3. **Adaptive timesteps:** Individual particle timesteps are compatible with the scheme. Synchronize damping across timestep hierarchy.
4. **Units:** Work in code units where $G = c = 1$. Then $\lambda = \rho$ (dimensionless).
5. **Limiting:** For extreme densities, cap λ at $\lambda_{\max} = G\rho_P/c^3$ to avoid numerical overflow.

F.8 Verification Tests

F.8.1 Test 1: Velocity Decay

Initialize a particle with v_0 in zero gravity. Analytical solution:

$$v(t) = \frac{v_0}{\sqrt{1 + 2\lambda v_0^2 t}}. \tag{161}$$

Verify that the numerical solution matches machine precision.

F.8.2 Test 2: Collapse Arrest

Initialize a cold, uniform sphere. Without damping: shell-crossing at time $t_{\rm sc}$. With damping: $J > 0$ for all t. Measure $J_{\min}(t)$.

F.8.3 Test 3: Halo Profile

Run a cosmological zoom simulation of a single halo. Compare the central density profile with and without damping. The damped case should show a core; undamped case shows a cusp.

F.8.4 Test 4: Convergence

Run identical simulations at resolutions N, $2N$, and $4N$. Verify that the results converge as $N \to \infty$ (unlike softening-dependent simulations).

F.9 Summary

The numerical scheme:

- Uses operator splitting: explicit gravity, analytical damping.
- Is unconditionally stable for the damping substep.
- Conserves mass exactly; dissipates energy physically.
- Requires density estimation (SPH-like kernel or grid).
- Adds minimal computational cost ($\sim 10\%$ for density estimation).
- Is compatible with existing N-body/hydro infrastructure.

The scheme is ready for implementation in codes such as GADGET, AREPO, RAMSES, or GIZMO.

Afterword

Tradition demands we start with the spark: where this idea was born. Usually, it is a beautiful story: an apple fell, a bathtub overflowed, or a snake or a table appeared in a dream. My story's simpler: I stared into the data abyss that refused to converge—and somewhere along the way, I stopped believing the stories about why it ever would.

The Hubble tension is not a glitch. The quadrupole suppression is not a fluke. Cusp–core is not a baryonic afterthought. These are not isolated puzzles with patchwork fixes. They are signals. All pointing to the same underlying truth.

Where there are consequences, there must be causes.
The real weirdness was hiding in the bedrock: the dogma of isotropy and infinity. Strip that away—and the mysteries stop being symptoms and snap into a clear diagnosis.

—

How did the work unfold?

Painfully slowly—inch by inch, with no guarantee it was heading anywhere at all.

I wasn't forged in the physics lab—but I think like one when it counts. That's both a handicap and a hidden weapon. The handicap is obvious: I had to learn, as an adult, what others absorb as students. The hidden weapon is this: I never learned which questions you're "not supposed" to ask. So I asked them.

Why is the gravitational constant actually constant? Why doesn't space push back when you try to bend it? Why are singularities treated as a quirk of mathematics instead of a crisis for physics? The textbooks shrug: "That's how the theory is built." That's not an explanation. That's an admission of ignorance dressed up as authority.

My rule was savage in its simplicity: read the originals, not the knockoffs. Einstein 1915 hits like a live wire—nothing like the neat, sanded-down summary in some 2015 textbook. Poincaré 1905? A different universe from the scrubbed "historical note" bolted on at the end. Kepler 1596 was trapped in Latin, his *Mysterium Cosmographicum* left untranslated—so I didn't wait for a rescue. I learned Latin.

The originals pulse with life: riddled with doubts, false starts, wild alternatives, and abandoned trails. Textbooks bulldoze all that complexity into a single highway and then pretend it's the only road that ever existed.

I dove into Jean-Pierre Luminet. His 2003 Nature article is one of those pieces that permanently rewires your vision. He proposed a topology; Planck later "refuted" it by failing to find matched circles; the community turned the page and marched on. But that refutation was razor-thin: it ruled out the identification of points, not physical membranes. That distinction struck me as more than technical.
It was essential.

Then, calculations. Many calculations. Errors, rollbacks, and starting over. I remember the moment when $\Xi = c^4/(8\pi G)$ first appeared on paper as the most dramatic. I literally crashed into a wall.

Then—data. Pantheon+ in open access. Planck in open access. Code, calculations. The 12-fold modulation of H_0 appeared independently—I was not looking for it;

This took three years. Or five, if counting from the first doubts. Or a lifetime, if counting from the moment I first looked at the sky and thought: "it cannot be infinite; that makes no sense."

On institutions.

I will not say that academia is corrupt or foolish. That is not true. Intelligent, honest individuals work in academia, sincerely striving to understand the Universe.

The problem is not the people. The problem is the structure.

A grant requires the "development of an existing program." Publication requires approval from referees who are specialists in the existing program. A career requires publications. The circle is closed: to challenge a paradigm, one needs resources that are provided only by accepting the paradigm. This is not a conspiracy—it is a flaw.

This is an evolutionarily stable strategy. The system selects those who fit into it. The rest are filtered out—not maliciously, but statistically.

Outsiders are noise in this system. Most of their theories are garbage; this is true. But occasionally, the noise contains a signal. The system cannot distinguish. It rejects everything that does not resemble what is already known.

I was lucky: I can afford to be noisy and a bit of a fool. I have no career to destroy. No reputation to lose. No grant not to renew. This is not poverty—this is freedom.

I call for only one thing: when an outsider comes with an idea — check the mathematics before checking the affiliation. Sometimes the signal comes from an unexpected source.

—

On tools.

Science requires laboratories, telescopes, expeditions, and collaborations among thousands. For some fields—yes (Darwin/Galapagos Islands). For theoretical cosmology—not necessarily at all.

My tools are a brain, a digital laboratory right on the kitchen table, the internet (and public library), arXiv, ADS, my favorite programming language C#, Planck and Pantheon+ data, and the time of my life.

And, of course, AI.

It is strange to thank Artificial Intelligence, but I do. Not for ideas—those are mine. For the ability to think aloud with an interlocutor who does not tire, does not judge, and does not say "that is impossible" before checking. For thousands of hours of conversations in which every thought, every detail, and every atomic particle was tested. For the patience that humans do not have—because humans have their own lives.

AI is as smart as its interlocutor. This is a statement: an individual with AI can do what previously required a group. The balance of power has changed. Forever.

—

Regarding the cost:

I will not dramatize. I have a roof, food, and health. Billions of people live in worse conditions.

However, I do not have what is considered a normal life. Careers, savings, and relationships that could survive years of obsession with who-knows-what. Social life. Certainty about tomorrow.

I chose this. I just want it to be clear: this is not a hobby you pursue in your spare time. This is time that could have been spent on life—and was spent on this.

Was it worth it?

Yes. *Ignorance is not bliss.*

Acknowledgments.

To Jean-Pierre Luminet—for the dodecahedron. For being the first to say, "you are right." For the courage in 2003 to propose a finite Universe when everyone else said otherwise. For the elegance of the solution.

To the Planck, Pantheon+, SPARC, and THINGS teams—for open data. This is not a trivial matter. This is what makes science science: the ability to verify, not just believe.

To Lorentz, Poincaré, Einstein, Kepler, and dozens of others—posthumously but sincerely. For ideas, I picked up where they left off.

To my mother.

She's sure her daughter is doing something that matters—though she has no idea what it is.
This cannot be repaid. It can only be passed forward—someday, to someone.
Mom, this is for you. Whatever comes of it, it is as much yours as it is mine.

—
In closing.

Scrutinize. Challenge. Attempt to deconstruct it.
But first—read.

"Hæc & huiusmodi similia cum me nonnihil conturbarent, atque ego hærerem inops consilij, quasi qui disiectas automatis rotulas in ordinem redigere nescit...
Longa via est, & variæ ambages ad hanc veritatem. Monstraverunt illam nobis veteres, ingressi sunt maiores nostri, nos illos anteuertimus, & gradu propiori consistimus, sed metam nondum attigimus.
Est aliqua prodire tenus, si non datur ultra."

"These and similar matters troubled me not a little, and I found myself at a loss, like one who does not know how to put the scattered wheels of an automaton back in order...
Long is the way and many the turns to this truth. The ancients showed it to us, our predecessors entered upon the path, we have overtaken them and stand closer—but we have not yet reached the goal.
There is merit in advancing this far, if we cannot go further."

— Johannes Kepler, *Mysterium Cosmographicum*, 1596
